ABSTRACT
The development of a distributed simulator requires knowledge and skills that might be unavailable or difficult to acquire. Bringing model-driven approaches to the development of distributed simulators contributes to reduce both the need for specific skills and the development effort. To support this innovative development methodology, we introduce a layered simulation architecture named SimArch that allows to define simulation models that can be transparently transformed into simulation programs ready to be executed in a distributed (or local) mode.

SimArch defines layers of services at increasing levels of abstraction on top of the execution environment, thus allowing developers to build distributed simulators without explicit knowledge about the execution environment (local/distributed) and the specific distributed simulation infrastructure (e.g., HLA).

In order to show the effectiveness of the proposed approach, SimArch has been provided with an Extended Queueing Network (EQN) simulation language, which has been applied to the development of an example distributed simulator in the computer network domain.

1. Introduction
Distributed simulation brings well-known advantages with respect to local simulation, mainly in terms of resource availability and reusability [1]. The availability of more memory and computational power can indeed allow the efficient execution of simulation programs that could not be run on a single machine and the possibility to build a distributed simulator by federating existing simulators enables the effective reusability of already developed simulation programs. On the other hand, the implementation of a distributed simulator is far from being easy and effortless, and very often distributed simulators are to be developed by appropriately adapting existing simulation components that have been developed for local execution [2].

Although much attention has been devoted to minimize the development effort by addressing interoperability and reusability issues, the ease (i.e. the adaptability) with which a local simulator developer can approach distributed simulation has not been considered. In order to address such a problem, we introduce a layered architecture named SimArch that exploits simulation approaches based on the precepts recently introduced in the model-driven development field [3].

Model-driven development is simply the notion that it is possible to build an abstract model of a system that we can then transform into more refined models and eventually into the system implementation. In the proposed approach, model-driven development is applied to distributed simulation by use of SimArch, which allows to develop a simulator by simply defining a simulation model that can be effortlessly transformed into a simulation program ready to be executed in a distributed (or local) mode.

SimArch defines a set of layers at increasing levels of abstraction on top of a distributed computing infrastructure (HLA in our case [4]) to allow the simulation developer to deal with simulation component logic issues only, without explicitly focusing on the specific (distributed or local) execution environment and simulation infrastructure. In such a way, SimArch brings several advantages in terms of simulation component reusability and effort reduction.
In order to show the effectiveness of the proposed approach, SimArch has been provided with an Extended Queueuing Network (EQN) [5] simulation language. Such a language has been defined by developing various software libraries that implement the services provided by the different layers of SimArch [6] [7] [8].

The paper is organized as follows. Section 2 briefly illustrates the related work, and Section 3 gives the description of the proposed architecture. Section 4 describes the EQN language built on top of the SimArch layers, and Section 5 illustrates its application to the development of an example distributed simulator in the computer network domain.

The example application has been carried out by first defining the EQN model of a so-called catenet, and then showing how the EQN simulation modeling language defined on top of SimArch can be effectively used to develop both a local version and a distributed version of the catenet simulator, with a twofold motivation: comparing the effort or developing the local and the distributed simulators and providing confidence about the effectiveness of the proposed approach.

2. Related work

The simulation community has provided several contributions that aim at increasing the abstraction level of the simulation primitives in order to achieve effort savings and reusability when building distributed simulators. However, the adaptability, i.e., the ease with which a new distributed simulator can be derived from existing ones, has not been thoroughly addressed.

Some related research efforts can be found in [9] [10] [11] [12], which describe PDNS, DisSimJava, DEVS/HLA, and OSA, respectively.

PDNS is an extension of the popular ns-2 tool for running network simulation in a distributed mode. SimArch differs from PDNS in two main aspects. The first is that SimArch is application domain independent, and therefore it does not deal with computer networks specifically. The second is the uniform representation of the communication among entities, independently from their type (local-local, local-remote, or remote-local), while PDNS explicitly introduces the ghost node abstraction to locally represent the connections to remote entities.

The DisSimJava work presented in [10] is based on a view similar to SimArch, from which it differs for three major aspects: first, it is only a prototype with the implementation of communication entities but without synchronization; second, it does not identify a layered architecture that allows simulation components to be run on different implementations; third, it does not provide HLA-compliant implementations.

DEVS/HLA [11] and the associated definition of a simulation middleware [13] can also be considered as contributions similar to SimArch. The basic difference is that SimArch approaches the problem of enabling developers familiar with local simulation to easily switch to distributed simulation, with a more pragmatic solution inspired by the current trend of semi-formal modeling languages, like UML. Moreover, SimArch clearly defines the communication interfaces between the layers and, at the same time, allows the composition of any set of implementations of such layers. In the end, SimArch could also be used to provide a DEVS implementation [14].

Finally, OSA [12] has a broader scope compared to SimArch. OSA aims at providing a general framework to cover the activities involved in the definition, development, validation and execution of a discrete event simulators. SimArch, differently, focuses on a restricted sub-set of the above activities, but in a deeper way. SimArch partitions the provided simulation services into four independent layers, whose implementation can be effortlessly changed to accommodate different requirements or future needs.

In addition, SimArch is currently provided with jEQN [15], a very flexible Domain-Specific Language (DSL) [16] for the description of EQN models.

3. SimArch

Distributed simulation systems can be considered as composed of several layers, each introducing a more abstract set of simulation services on top of the underlying layer, the bottom one being the distributed computing infrastructure.

There are three main advantages for adopting this layering approach. The first is that the simulation model is decoupled from the specific execution environment, and then it can be reused across several simulation platforms. The second is that the layers’ implementations can be easily modified or replaced to accommodate custom deployment requirements (i.e. local or distributed deployment, performance optimization for given simulation workload, etc.). Finally, the third advantage is that simulation developers deal only with the high level simulation services, and therefore can focus on the model description rather than being involved in the typical intricacies of distributed simulators implementation.

The proposed layered simulation architecture SimArch consists of four layers [13] [8], each dealing with a specific distributed simulation issue.

Figure 1 illustrates the architecture layers, whose detailed description is given in [8].

In SimArch, the top Layer 4 is the layer where the simulation model is defined through the invocation of the simulation language primitives.

The primitives’ implementation, i.e., the components’ simulation logic and the model configuration services, are provided by Layer 3; while Layer 2 deals with the simulation components synchronization and communication, transparently for local and distributed environments. The distributed version of this layer uses in turn Layer 1 to achieve global time synchronization and provides communication with the remote simulation components.

Finally, Layer 1 provides a DES (discrete-event simulation) abstraction on top of the distributed computing infrastructure conventionally identified by Layer 0. Such bottom layer does not belong to SimArch and therefore the service interfaces between Layers 1 and 0 are not defined. In the case of a HLA-based implementation of Layer 1, such interfaces are subsets of the RTI-Ambassador and FederateAmbassador interfaces for the communication between Layers 1 and 0 and between Layers 0 and 1, respectively.
3.1 Data interfaces

The data interfaces define the access methods to the data exchanged between the layers. Specifying abstract data structures instead of concrete data structures decreases the level of layer coupling, and therefore allows layers’ implementation to be effortlessly modified or replaced.

SimArch defines the following data interfaces:

- **ComponentLevelEntity**: interface for local simulation entities (including their hierarchical composition);
- **Event**: interface for events scheduled between layers;
- **GeneralEntity**: a base interface for local and remote entities;
- **InputPort**: interface for received events;
- **Link**: interface for connecting input and output ports;
- **Name**: interface for the declaration of names in SimArch;
- **OutputPort**: interface for sent events;
- **Port**: interface for the common access to port internal data;
- **RemoteEntity**: interface for remote simulation entities;
- **Time**: interface for the representation of simulation time.

Each of the above defined interfaces is of immediate understanding and therefore not discussed further here. The reader is sent to [7] [8] for additional details.

3.2 Layers’ service interfaces

The service interfaces defines the communication paths between adjacent layers, in both directions. Layers 1 and 2 communicate through the **Layer2ToLayer1** (Figure 2) and **Layer1ToLayer2** (Figure 3) interfaces; similarly Layer 2 and 3 communicate through the **Layer3ToLayer2** (Figure 4) and **Layer2ToLayer3** (Figure 7) interfaces. At Layer 4, the simulator developers can describe their simulators by assembling Layer 3’s domain-specific components through the **Layer3UserInterface** (Figure 5), which is to be considered as **Layer4ToLayer3** SimArch interface.

In more detail:

The **Layer2ToLayer1** (Figure 2) interface allows communication from Layer 2 to Layer 1. The interface is defined through five services. The **initDistributedSimulationInfrastructure** and **postProcessingDistributedSimulationInfrastructure** services are general placeholders to allow the system set-up and the initial state recover after the simulation execution, respectively. The remaining three services provide the DES abstraction in the distributed system. In particular, **sendEvent** delivers the given event to the recipient at the specified time; **waitNextDistributedEvent** blocks the invoking thread until a distributed event is received, and **waitNextDistributedEventBeforeTime** blocks the invoking thread until either a distributed event is received or the specified time is reached by the distributed simulation.

The **Layer1ToLayer2** (Figure 3) interface allows Layer 1 to transparently schedule distributed events into the local system. This functionality, however, is split into two services, **scheduleEvent** and **scheduleSimulationEndEvent**, to further decouple Layers 1 and 2.

The communication from Layer 3 to Layer 2 takes place through the **Layer3ToLayer2** (Figure 4) interface, which is in turn composed of a user-oriented service set (**Layer3ToLayer2UserInterface** - Figure 5) and a developer-oriented service set (**Layer3ToLayer2DeveloperInterface** - Figure 6).

The **Layer3ToLayer2UserInterface** groups the services that enable the simulation language user (simulator developer at Layer 4) to produce the simulator. The interface provides two basic configuration and simulation management services: **registerEntity**, to add a simulation component to the simulator; and **start**, to make the execution container start the simulation execution.
The Layer3ToLayer2DeveloperInterface provides DES services to build the simulation logic of each component. The services are of four types: waitNextEvent, to block the component execution until an event is received; hold, to block the component execution for \( t \) simulated time units; holdUnlessIncomingEvent, to block the component execution for \( t \) simulated time units or until an event is received, whichever first; and, finally, a send method to deliver events at a given simulated time.

Figure 7 Layer2ToLayer3 interface [8]

The body method encapsulates the simulation logic of the component, and therefore it is invoked when the component container is started. This method is made up of the Layer3ToLayer2 service calls (i.e. hold, waitEvent, etc.) in addition to the operations on the component state variables (e.g. the length of a queue, the state busy/free of a service center, etc.). The other services are of immediate understanding and therefore not further discussed here.

### 3.3 Layers’ implementation

To provide evidence of the SimArch usefulness, we designed and developed a Java library for each of the layers (1 through 3), and produced an example simulator at Layer 4, as described in Section 5. The three libraries have been named DDESoverHLA (at Layer 1), SimJ (at Layer 2) and jEQN (at Layer 3).

DDESoverHLA implements the Layer2ToLayer1 interface on top of HLA and CORBA-HLA [17].

**SimJ** provides a framework for the local development of simulation components that can be equivalently deployed in local and distributed simulations.

Finally, **jEQN** defines a DSL [16] for the definition of EQN models and for the implementation of EQN simulators on top of SimArch. jEQN is currently implemented as a Java library though its design features allow to make use of any other object oriented language [15].

The language is defined by the Layer 4’s services (i.e. Layer3ToLayer2UserInterface’s services) in addition to the syntax of the proper jEQN simulation components. This in turn includes the components’ name, assigned according to the EQN standard taxonomy (e.g., user sources, waiting systems, service centers, routers and special nodes), and support components for their parameterization (e.g., the policy framework, see below) and for the data structures (e.g., User, Queue, etc.).

jEQN has been designed to encapsulate the simulation logic only within the simulation components and to leave undefined the parameters that do not directly affect it. In such a way, each simulation component exhibits a high degree of cohesion and it can be easily reused across the several values the parameters might assume. The parameters are designed and developed as support components, in order to decouple the jEQN simulation components from the parameters themselves and to allow a flexible configuration of such components.

jEQN defines the following types of support components:

- **cat 1.** parameters used to take decisions;
- **cat 2.** parameters that provide a sequence of values;
- **cat 3.** parameters that provide storage support.

Parameters like the routing policy (decision: where to route a given user), the termination condition (decision: assess whether or not the source has to terminate), the enqueueing policy (decision: where to insert a given user), etc., belong to the first category. For these parameters, jEQN defines a framework and a taxonomy within which each policy has to be classified according to the use and the type of the following four parameters [15]:

- **I:** the type of implicit input;
- **S:** the type of the policy state data;
- **T:** the type of the explicit input;
- **D:** the type of the decision.

Where implicit input is the input taken at policy instantiation time, the policy state is the internal state of the policy and the explicit input is the data for which the decision has to be taken (the meaning of the type of decision being straightforward).

The second category includes parameters like interarrival times, user generators, etc.

Finally, the third category defines parameters for the components that provide storage support for the simulation, such as queues.
The definition of an EQN model is carried out by identifying: the EQN components (e.g.: user sources, waiting systems, etc.), their properties (e.g.: enqueueing policy, routing policy, user interarrival rate, etc.), and their connections.

The development of a jEQN simulator, either local or distributed, follows the same process, and therefore it contributes to bring the model-driven development into the system simulation.

Further jEQN modeling details are available in [15].

5. Computer network distributed simulation with jEQN

Figure 8 illustrates the example system that has been simulated using jEQN. The system is a so called catenet, composed of:

(a) two separate LANs, the first (LAN1) a token ring that connects Host A, and the second (LAN2) an Ethernet that connects Host B

(b) two gateways GW1 and GW2, that connect LAN1 and LAN2 to the WAN, respectively,

(c) the WAN, an X.25 packet switched network.

The objective of the simulation study is to evaluate the end-to-end delay between Host A and Host B, the former in the LAN A and the latter in the LAN B. Host A acts as a client and Host B as a server.

We developed both a local version of the simulator and a distributed one, in order to:

- validate the results (i.e., the end-to-end delay) obtained from both the local simulator and the distributed simulator through direct comparison with already available data (see [18]) and
- compare the effort needed to build the distributed simulator with respect to the one required for developing the local simulator.

5.1 Model definition

It is assumed the interaction between the client (Host A) and the server (Host B) is based on message exchanges carried out by packet flows over the various components of the catenet. The packet flow involves several technologies (Token Ring, X.25, Ethernet) and thus several mechanisms are necessary to deal with heterogeneity, namely:

- (m1) protocol conversion, from the transport layer protocol TCP, to the network layer protocol IP, to the data-link layer and physical layer protocols (and vice versa), in either direction from Host A to Host B, with the IP to X.25 (and vice versa) protocol conversion at the gateway level,

- (m2) packet fragmentation and re-assembly at many protocol conversion interfaces,

- (m3) window-type flow control procedure operated at transport layer by protocol TCP for a fixed window size of value C (for the sake of simplicity no varying window sizes are considered, nor the use of congestion-avoidance algorithms).

Figure 9 gives a more detailed view of the packet flow in the system and puts into evidence the work performed by the network components in order to deal with mechanisms m1, m2 and m3, when transferring data from Host A to Host B (a symmetrical flow holds when transferring data from Host B to Host A).

In the A-to-B flow, illustrated in Fig. 9, the packets are originated by the Host A application layers in TCP format and then translated into IP format by the Host A network layers to enter LAN1. From LAN1 they exit in LLC/MAC802.5 format to enter GW1 that fragments them into X.25 format to be accepted by the WAN. Vice versa for the GW2, where X.25 packets are re-assembled into LLC/MAC802.3 format for LAN2 and from there into the IP format and then in the TCP format by the Host B network layers. The token pool in Figure 9 is introduced to represent the window-type flow control procedure implemented by TCP between the source and the sink. For a window size C, the pool consists of C tokens, and so up to C consecutive TCP packets can GET a token and be admitted to the catenet. Non-admitted packets are enqueued outside the catenet. On the other hand, each admitted packet RELEASEs its token at the sink entrance, thus allowing another packet to enter. Further details about the definition of the model of the catenet system can be found in [18].

---

1 The term “catenet” is an obsolete term used to indicate a system of packet-switched communication networks interconnected via gateways [21]. It is here used for the sake of brevity to denote a computer network speaking the Internet protocol.
5.2 Design and implementation details
The implementation of the local version of the simulator consists of the following three steps:

1. Instantiate the Layer 2 local container (the simulation engine) to execute the jEQN components.
2. Define the jEQN components of the model by:
   a. Defining the jEQN entities
   b. Defining the connections among entities.
3. Start the container execution.

It is worth noting that the jEQN components (Layer 3) are automatically registered with the underlying Layer2 container that executes them.

Step 1 and step 3 can be simply carried out by use of the SimArch services. Step 2, the core activity for the development of the simulator, is carried out by use of a procedure that can be partially automated to obtain jEQN components from the detailed definition (Layer 4) of the EQN model.

For the sake of brevity, we report here jEQN development details of only the Token Ring (LAN1) part of the catenet. Figure 10 shows the LAN1 model, which reflects the typical behavior of local area networks of Token Ring type. The queueing policies at each queue, including the Token allocation queues, are of FCFS (First Come First Served) type, while the service centers are of non-preemptive type with Gaussian service times. The users (packets) flow into the main loop (from the allocTok node to the routing node) until the number of the frames they are composed of has been processed.

The implementation of the simulator is carried out by defining a jEQN component for each corresponding element in Figure 10. The model thus consists of six jEQN waiting systems, three service centers, one router, two allocate nodes, one release node, one destroy node, two set nodes, and finally two pools of tokens.

The configuration of those components is carried out by applying the jEQN parametrization procedure that identifies, for each component, appropriate parameters within the three jEQN categories of parameters described in Section 4.

As an example, each queue in the model is defined through an enqueuing policy (cat 1 parameter) and a storage structure (cat 3 parameter). The enqueuing policy can be defined through the jEQN policy framework by first classifying the policy according to the jEQN policy taxonomy and then identifying the parameters [15]. The FCFS enqueuing policy can be modelled as a policy that depends on the implicit input parameter (the queue), which has no internal state, no explicit input, and whose returned decision data is the index within the queue. This policy is easily implemented by returning as “decision” the length of the queue.

As regards the storage parameter, the model implicitly considers all the queues as infinite single FCFS queues. In jEQN, this can be done by first choosing a concrete data structure implementing the Java List interface, and then setting up both the storage parameter of such structure and the enqueuing policy. The jEQN modularity and flexibility allows the introduction of more complex storage structures (e.g., multiqueue with different enqueuing policies and capacity, etc.), at no additional costs.

The service centers are of non-preemptive type, according to the model definition, and their parameters are limited to the type of service, i.e. to the sequence of numbers that simulate the introduced delay. The Gaussian property of service centers is set by use of the jRand framework [19], by passing a Gaussian pseudo-random generator at instantiation time.

The router is allocated with the proper routing policy. This policy is once again defined by use of the jEQN policy framework. It depends on the parameter T, explicit data, which is of type User, and returns a decision of type Integer, which indicates the port id through which the processed User has to be forwarded. The implementation of this policy can be easily obtained by testing whether the number of frames is equal to zero or not. In the
former case, the returned port id is the id of the port connected to the destMsg node, whereas in the latter case the id is returned of the port connected to the allocTok node.

The remaining jEQN components, corresponding to nodes for allocating and releasing tokens, do not need to be parametrized.

The simulation model definition of the LAN1 is completed by connecting the components as in the model specification. To this purpose, the jEQN implementation of the Link SimArch interface can be used to instantiate links and to register components’ ports as in [6]. For example, the allocTok waiting system has its user output port connected to the getToken service center, which is in turn connected to the following setSender special node, and so on for the remaining components.

Now assume all the remaining parts of the catenet have been in a similar way jEQN-modeled, to obtain the complete local version of the simulator.

The implementation of the distributed version of the simulator is easily obtained from the corresponding local version. This further remarks how the abstraction layers introduced by SimArch actually allow the model-driven development of distributed simulators, as they are almost not aware of the distributed execution environment.

In general, the implementation of a SimArch distributed simulator follows four steps, for each (distributed) submodel:

1. Instantiate the Layer1 and Layer2 implementations;
2. Define the submodel by:
   a. Defining the entities:
      i. Local simulation entities as in the local simulator;
      ii. Remote simulation entities by declaring remote references through the proper SimArch interface;
   b. Defining the connections:
      i. Local connections among local entities as in the local simulator;
      ii. Remote connections (outcoming connections) from local entities to remote entities.
3. Activate the Layer2 container.

In our example, assume we decided to partition the Fig. 9 model into three distributed submodels (Submodel 0, Submodel 1 and Submodel 2), as shown in Figure 11.

By use of Simarch it is straightforward to define submodels as follows:

Submodel 0 will consist of the HostA and LAN1 entities and their local connections, as in the local simulator, in addition to a remote reference to GW1 and a remote connection between the LAN1 entity and GW1.

Similarly, Submodel 1 will consist of the GW1, WAN and GW2 entities and their local connections as in the local simulator, in addition to two remote references to the LAN1 and LAN2 entities with the related remote connections to GW1 and GW2, respectively.

Finally, Submodel 2 will consist of the HostB and LAN2 entities and their local connections, as in the local simulator, in addition to a remote reference to GW2 with the related remote connection.

Which ends the distributed simulator definition.

5.3 Simulator validation

The distributed simulator validation is carried out through comparison of exact values and global trend of the end-to-end delay in the local and distributed case. The end-to-end delay is measured by increasing values of the arrival rate \( \lambda \) (packets/sec) from the source for different values of the window size (C = 4, 7 and 12 packets). The simulation statistics are collected according to the batch method, with initial bias removed, in 5000 simulated seconds. The local simulator results are shown in Figure 12.
simulation logic can be specified by use of few basic simulation services, which enable the simulator developers to abstract from the details of the underlying (local or distributed) execution environment.

In this paper we have introduced SimArch, a layered architecture that brings model-driven development into the simulation field. In order to prove the effectiveness of the SimArch concept, a set of software libraries that implement the different layers of the architecture have been developed and several simulators have been produced. To this scope SimArch has been provided with an Extended Queueing Network (EQN) modeling language, which has been then used to develop an example case of distributed simulation in the computer network domain.

The example case has been validated through direct comparison with results obtained from previous studies, and has shown that, by use of SimArch, the distributed simulator can be easily built from the definition of the simulation model, either from scratch or by slightly modifying a local version of the same simulator.
