Window Flow Control in Stochastic Network Calculus –
the General Service Case

ABSTRACT
The problem of Window Flow Controlled (WFC) systems
has been analysed successfully in Deterministic Network Cal-
culus (DNC). While many results of DNC have been carried
over to its stochastic extension, the problem of WFC sys-
tems has not been solved so far. This paper presents the
first approach to analyse WFC in the context of Stochas-
tic Network Calculus (SNC) for a general service inside the
feedback loop of the controller. The key idea is to keep
track of how much the service deviates from being subad-
ditive. The new method is illustrated in numerical examples
and its properties are discussed.

Stochastic Network Calculus, Feedback, Flow Control

1. INTRODUCTION
Stochastic Network Calculus (SNC) has matured in recent
years to provide an alternative method for performance anal-
ysis of stochastic queueing systems (see e.g. [15, 13, 9]).
Many results from the deterministic network calculus (DNC)
have been transferred into the stochastic domain, some have
been rather immediate some have required considerable ef-
fort (e.g., deriving the end-to-end service [7]). One major
remaining open issue is the stochastic analysis of feedback-
based systems, such as Window Flow Controlled (WFC)
transport protocols, e.g. TCP. While there are very ele-
gant solutions for WFC in the deterministic setting [1, 5,
16], WFC in SNC has been identified for some time already
as a very challenging open research question [15, 12, 13, 8].
Moreover, being able to analyse WFC systems in SNC would
be very relevant to open up new application areas for SNC
such as modelling smart grid systems [14], for instance.

In this paper, we present an approach to analyse WFC in
SNC under very general assumptions. As we demonstrate
below, as long as the service in the feedback loop is subad-
ditive the analysis is a rather direct transfer from DNC (see
[3] for a detailed discussion, where especially the continu-
tous time case needs care, though). Yet, the assumption of
a subadditive service inside the feedback loop is restrictive
and there are several scenarios where subadditivity cannot
be assumed; most prominently, this is the case if a tandem of
servers has to be traversed. This is why we tackle the hard
case of general service in the feedback loop in this work.

The key idea of our approach is to stochastically control
how far the service deviates from being subadditive and cast
this into the setting of MGF-calculus [6, 11], a branch of
SNC, as further contribution to the violation probabilities
of the performance bounds. We demonstrate the method by
providing some numerical results in case of a server in the
feedback loop that is not subadditive and would thus not be
analysable by direct methods (compare [3]).

2. NOTATION AND SOME BASIC RESULTS
First, we provide the notation and some basic results of (de-
terministic) network calculus. For further details one can
also refer to [4, 6]. For ease of presentation we assume a
discrete time model throughout this work, see [3] for results
on continuous time.

We start by defining (arrival) flows, which represent a fluid
stream of data. These flows enter and depart service ele-
ments.

DEFINITION 1. We denote an arrival flow by its cumula-
tives $A$; i.e., $A(t)$ units of data arrive in the interval $[0, t]$.
The bivariate extension of $A$ is defined by:

$A(s, t) := A(t) - A(s)$.

Note that flows are always additive, i.e.

$A(s, t) = A(s, r) + A(r, t)$

for all $r, s, t$.

We introduce two service descriptions here, one for the uni-
Figure 1: A window flow controller: the input $A$ is throttled at the $\land$-element. The departures of the system are $C$ and the feedback-loop consists of the dynamic $U$-server, an unspecified service element and a window-element. The star is a placeholder for any input-output pair $A, B$.

The following is crucial for the end-to-end analysis of networks consisting of several service elements.

Theorem 3. Consider two service elements, such that the output of the first service element is the input to the second. If both service elements have a service curve $U_i$ (for $i = 1, 2$), the system also has a service curve, given by $U_1 \otimes U_2$ (is a dynamic $U_1 \otimes U_2$-server).

The second network-operation we give here is central to this work. It describes how a WFC system as presented in Figure 1 is handled. In this feedback system, the original input $A$ is fed to a throttle-element first, which governs how much data is admitted to the inside of the system (the feedback-loop). This is realized by taking the minimum of the input $A$ and the output of the service element at any time, such that:

$$B(t) = A(t) \land D(t).$$

Such systems are studied for example in $[1, 5, 16, 6]$. We formulate from there the following theorem:

**Theorem 4.** Assume the whole feedback-loop in Figure 1 is described by a service curve $U_{fb}$ (is a dynamic $U_{fb}$-server). The throttle element $\land$ has a service curve $U_\land$ (is a dynamic $U_\land$-server), with:

$$U_\land(t) = \bigwedge_{k=0}^{\infty} U_{fb}^{(k)}(t), \quad U_\land(s,t) = \bigwedge_{k=0}^{\infty} U_{fb}^{(k)}(s,t).$$

Here the notation $U_{fb}^{(k)}$ stands for the $k$-fold self-convolution of $U_{fb}$. Further, for any $U$ we define $U^{(0)}$ to be the neutral element of the convolution: $U^{(0)}(t) = 1(t) = \infty$ for all $t > 0$ and $1(0) = 0$ (for the bivariate case we have $1(s,t) = \infty$ for all $s < t$ and $1(t) = 0$ for all $t$, respectively). The expression $\bigwedge_{k=0}^{\infty} U^{(k)}$ is known as the subadditive closure of service $U$. As the name suggests the subadditive closure of a service description is subadditive. Further, we have for any subadditive $U$:

$$\bigwedge_{k=0}^{\infty} U^{(k)} = 1 \land U.$$

To complete the analysis of the feedback system in Figure 1 we apply Theorem 4 and Theorem 3 and get a service description for the whole system by:

$$U_{sys} = U_\land \otimes U.$$

This service description can then be used to derive performance bounds, like end-to-end-delay, as detailed later.

In network calculus one typically assumes systems to be empty at time zero, i.e., for all participating flows holds $A(0) = 0$. The window element in the feedback-loop serves two purposes: 1) it kick-starts our system, by initially admitting a certain amount of data to $U$ and 2) it controls how much data is present inside the feedback-loop, thus guaranteeing a maximum backlog, which may occur on any element inside of it.

**Definition 5.** A window element $\Sigma$ is a function from $N_0$ to $R^+_0$, such that for any input-flow $A$ it produces an output $B$:

$$B(t) = A(t) + \Sigma(t)$$

$$\Sigma(s,t) \geq -A(s,t) \quad \forall s \leq t.$$

We further define the bivariate $\Sigma(s,t)$ as for flows.

The window elements relays its input $A$ without delay and adds the window size $\Sigma$ to it. The constraint (4) enforces, that the output $B(s,t)$ of a window element cannot be negative (the window element can negate the whole input, though, by reducing its window size). Note that a window-element
We point out here that none of the state-of-the-art methods is able to describe the service process resulting from Theorem 4 efficiently. This is why the solution of WFC systems eluded stochastic network calculus, so far.

3. PROBLEM EXPOSITION

Subadditivity plays an important role when analysing WFC systems, as the throttle’s service is just the subadditive closure of the elements inside the feedback loop. Hence, feedback-loops containing subadditive elements are much easier to analyse. We present this situation now in detail.

We look at a feedback loop which contains a subadditive service element $U$ (lying on the path from the sender to the receiver) and a window-element (lying on the return path). Such a system can be easily analysed, by applying the most general result concerning WFC systems as found in the textbook of Chang [6]. To that end, denote the space of bivariate functions which are monotonically increasing in their second variable as $\tilde{F}$. We see immediately that all flows and all dynamic-server descriptions lie in $\tilde{F}$, as they fulfill $F(s,t) \leq F(s,t')$ for all $t \leq t'$.

DEFINITION 8. An operator $\pi : \tilde{F} \to \tilde{F}$ is called $\sigma$-additive if:

$$\pi \left( \bigwedge_{n=1}^{\infty} F_n \right) = \bigwedge_{n=1}^{\infty} (\pi(F_n)),$$

where $F_n$ is any sequence in $\tilde{F}$ and the infima are understood pointwisely.

One can easily verify that the space of $\sigma$-additive operators is closed under taking countable minima and compositions. Further they distribute over countable minima:

$$\left( \bigwedge_{n=1}^{\infty} \pi_n \right) \circ \pi = \bigwedge_{n=1}^{\infty} (\pi_n \circ \pi), \quad \pi \circ \left( \bigwedge_{n=1}^{\infty} \pi_n \right) = \bigwedge_{n=1}^{\infty} (\pi \circ \pi_n).$$

An example of a $\sigma$-additive operator is the convolution with some bivariate $U \in \tilde{F}$, defined by $\pi_U(A) := A \circ U$. Other examples needed for our specific feedback system are

$$\pi_{U}(A) := A,$$

$$\pi_{U+w}(A)(s,t) := \begin{cases} A(s,t) & \text{if } s \neq 0 \\ A(0,t) + w & \text{if } s = 0 \end{cases}$$

where $w \in \mathbb{R}$. The above operators represent the identity operator and a window-element, respectively; their $\sigma$-additivity as well as the following properties are easy to verify:

- $\pi_{U+w}$ commutes with $\pi_U$, i.e. $\pi_U \circ \pi_{U+w} = \pi_{U+w} \circ \pi_U$.
- $\pi_{U+2w} = \pi_{U+2w}$, and $U$ is subadditive with $U(t,t) = 0$ for all $t$ if $\pi_U$ is idempotent, i.e. $\pi_{U}^2 = \pi_U$.

The whole feedback loop can be expressed by successively applying $\sigma$-additive operators and it is a $\sigma$-additive operator...
itself: \[ \pi_{fb} := \pi + \pi_U, \]
i.e. \( D = \pi_{fb}(B) \). The relations between the flows in Figure 1 are hence given by:
\[ B(t) = A(t) \land \pi_{fb}(B)(0,t). \] (8)
Lemma 5.7.2. in [6] can be applied resulting in \( B \geq \pi_{fb}(A) \) for any \( B \) fulfilling \( B \geq A \land \pi_{fb}(B) \), where \( \pi^*_fb = \pi_c \land \bigwedge_{n=1}^{\infty} \pi^n_{fb} \) is the closure of \( \pi_{fb} \).

We show now that \( \pi^*_fb \) is tractable when considering a subadditive \( U \) together with a window-element.

**Example 9.** Applying the above properties to \( \pi_{fb} \), we observe that
\[ \pi^n_{fb} \geq \pi + \pi_U. \]
And for the closure of \( \pi_{fb} \)
\[ \pi^*_fb \geq \pi_c \land \bigwedge_{n=1}^{\infty} \pi + \pi_U = \pi_c \land \pi_U. \]

Applying the result of Chang we have for the departures \( C \) of the feedback system:
\[ C(t) \geq \pi_c(B)(0,t) \geq \pi_U \land \pi^*_fb(A)(0,t) \]
\[ = \bigwedge_{n=0}^{\infty} \pi_U \land \pi^n_{fb}(A)(0,t) \]
\[ \geq \bigwedge_{n=0}^{\infty} \pi + \pi_U(A)(0,t) = \pi_U(A)(0,t) \]
We use the distributivity of \( \sigma \)-additive operators in the second line. We see that the whole system behaves, just like the unthrottled one. With given MGF-bounds on \( A \) and \( U \) we can use this bound on \( C \) to produce stochastic performance bounds, as in Theorem 7.

The above example makes the role of subadditivity clear: without \( U \) being subadditive, we would not have \( \pi^*_fb = \pi_U \) and the description of \( \pi^*_fb \) would include \( \pi^*_nU \). The repeated application of \( \pi_c \) prevents deriving stochastic performance bounds as above. Note further, that the window-element causes only minor difficulties, as its operator commutes with \( \pi_U \).

The most important example for a non-subadditive \( U \) is a service, which results from applying Theorem 3. How one can preserve subadditivity instead for a concatenation of service elements is discussed in [3]. However, preserving subadditivity in that way comes at the cost of a decreased service.

We now leave the notations of \( \sigma \)-additive operators, and take a step back to have a closer look at subadditivity in the most simple scenario. For this discussion we retreat to the univariate case and let the placeholder in Figure 1 be empty. Further, we assume a window-element of fixed size, such that \( U_{fb} = U + \Sigma \).

As the subadditive closure of the feedback-loop appears in the solution of the Theorem 4, subadditivity of the service curve \( U \) and how much is “missing” to it are crucial questions in WFC systems. Assume we can give the following bound, describing by what quantity a service curve \( U \) fails subadditivity:
\[ U(t) - U \lor U(t) \leq b \quad \forall t \in \mathbb{R}_+^+. \] (9)
Or, written differently:
\[ U^{(2)}(t) \geq U(t) - b \quad \forall t \in \mathbb{R}_+^+. \]
If we consider some \( U \) and \( b \) to fulfill Equation (9), we achieve for \( \Sigma \geq b \) the subadditivity of \( U + \Sigma = U_{fb} \), since
\[ (U + \Sigma) \lor (U + \Sigma)(t) = U^{(2)}(t) + 2\Sigma \]
\[ \geq U(t) - b + 2\Sigma \]
\[ \geq U(t) + \Sigma = U_{fb}(t). \]

A subadditive \( U_{fb} \), however means that \(^1\)
\[ U_{sys}(t) = U_{fb} \lor U(t) = (1 \land U + \Sigma) \lor U(t) = U(t). \]

This effect, that a system with a large enough window can be analysed as unthrottled, is well known and can for example be found in [1]. One can think of the window-element to compensate for how the service deviates from subadditivity.

### 4. WFC WITH GENERAL SERVICE

We revisit the solution of Theorem 4. Without further assumptions, we need to find an MGF-bound in the sense of (6) for the end-to-end service:
\[ U_{sys} = \left( \bigwedge_{n=0}^{\infty} (U_{fb}^{(n)}) \right) \lor U(s,t), \]
where \( U_{fb} \) represents the whole feedback-loop. Just applying the definition of the MGF we obtain
\[ \Phi_{U_{sys}(s,t)}(-\theta) = \mathbb{E}(e^{-\theta (U_{fb}^{(n)}) \lor U(s,t)}) = \mathbb{E}(\bigvee_{n=0}^{\infty} e^{-\theta U_{fb}^{(n)} \lor U(s,t)}). \]

A naive approach would be to use \( \mathbb{E}(X \lor Y) \leq \mathbb{E}(X) + \mathbb{E}(Y) \) for some positive random variables \( X \) and \( Y \), resulting in:
\[ \Phi_{U_{sys}(s,t)}(-\theta) \leq \sum_{n=0}^{\infty} \mathbb{E}(e^{-\theta U_{fb}^{(n)} \lor U(s,t)}). \]

This however is problematic, since finite representations, as in (6) for \( U_{fb}^{(n)} \) with \( n \to \infty \), are hard to achieve, even if \( U_{fb} \) consists of a single server \( U \) and the window element \( \Sigma \) only.

Remembering condition (9) we choose another path here. To fix notations, insert for the placeholder in Figure 1 a dynamic \( V \)-server, such that \( U_{fb}(s,t) = U \lor V(s,t) + \Sigma(t) \). We saw in the univariate case for \( b < \Sigma \) an easy solution to the feedback inequality. The same holds for the bivariate setting with a dynamic window; assume it holds for all \( s \leq t \):
\[ U \lor V(s,t) - (U \lor V)^{(2)}(t) \leq b \leq \Sigma_{min}(t) \] (10)

\(^1\)As they are \( \sigma \)-additive operators the convolution with a function is distributive over minima, i.e.: \((U_1 \land U_2) \lor V = U_1 \lor V \land U_2 \lor V\).
with $\Sigma_{\min}(t) := \min_{s \leq t} \{\Sigma(s)\}$. Then we have:

- $U_{fb} \otimes U_{fb}(s, t) = \min_{s \leq t} \{U \otimes V(s, r) + \Sigma(r) + U \otimes V(r, t) + \Sigma(t)\}$
- $\geq \min_{s \leq t} \{U \otimes V(s, r) + U \otimes V(r, t) + \Sigma_{\min}(t) + \Sigma(t)\}$
- $\geq U \otimes V(s, t) + (\Sigma_{\min}(t) - b) + \Sigma(t)$
- $\geq U_{fb}(s, t)$

and $U_{fb}$ is subadditive.

We use this property to achieve a service description for the whole system by:

- $U_{sys}(s, t) = U_{fb}(s, t) \otimes U(s, t) = \min_{s \leq t} \{U \otimes V(s, r) + \Sigma(r) + U \otimes V(r, t) + \Sigma(t)\}$
- $= \min_{s \leq t} \{U \otimes V(s, r) + U \otimes V(r, t)\} + \Sigma(t)$
- $\geq U \otimes V(s, t) + \Sigma(t)$
- $= U \otimes V(s, t)$

In (12) and we used the monotonicity of min-plus convolution: $U(s, t) \geq U \otimes V(s, t)$ for any $V$ with $V(t, s) = 0$ for all $s$.

So, under the assumption of (10) we obtain at least the same service for the throttled system as for an unthrottled one where the servers $U$ and $V$ would have to be traversed. Hence, we are interested in the probability of (10) happening and call that event $E$. With this information at hand we can analyse the whole system by:

- $\mathbb{P}(d_{sys}(t) > x) = \mathbb{P}(d_{sys}(t) > x \mid E)\mathbb{P}(E) + \mathbb{P}(d_{sys}(t) > x \mid \neg E)\mathbb{P}(\neg E)$
- $\leq \mathbb{P}(d_{U \otimes V}(t) > x) + \mathbb{P}(\neg E)$

where $\mathbb{P}(d_{U \otimes V} > x)$ can be calculated by applying Theorem 3 and Theorem 7.

We now discuss condition (10) and its corresponding probability. For ease of presentation, we leave the placeholder blank, i.e., $U \otimes V = U$.

One can rewrite (10) by:

- $\max_{0 \leq s \leq t} \{U(s, t) - U \otimes U(s, t)\} \leq b$,

which is just the expression we arrive at when bounding the buffer in bivariate deterministic network calculus, if feeding a “flow” $U$ in a dynamic $U \otimes U$-server. Such stochastically dependent systems can be analysed in MGF-Calculus by using Hölder’s inequality. For this assume some MGF-bounds of the form (5) and (6) for $U$ (we denote the $\sigma$ and $\rho$ corresponding to bound (5) by $\sigma$ and $\rho$ to distinguish them from the ones used in (6)). The probabilistic backlog bound in such a system is $(\frac{1}{p} + \frac{1}{q} = \frac{1}{p} + \frac{1}{q} = 1)$:

- $\mathbb{P}(q(t) > b) \leq \mathbb{P}(\max_{0 \leq s \leq t} \{U(s, t) - U \otimes U(s, t)\} > b)$
- $\leq e^{-\theta t} \sum_{s=0}^{t} \mathbb{E}(e^{\theta U(s, t) - U \otimes U(s, t)})$
- $\leq e^{-\theta t} \sum_{s=0}^{t} (\mathbb{E}(e^{\rho U(s, t)}) + \mathbb{E}(\rho U(s, t)))^{1/p} (\mathbb{E}(e^{\theta q U(s, t)}) + \mathbb{E}(\theta q U(s, t)))^{1/q}$
- $\leq e^{-\theta t + \theta q t} \sum_{s=0}^{t} e^{\rho U(s, t)} (1 - s) + \theta q (\mathbb{E}(e^{\theta q U(s, t)}) + \mathbb{E}(\theta q U(s, t)))^{1/q}$

We have used Chernoff’s inequality in the second line and Hölder’s inequality in line 3 and 5. If we assume, w.l.o.g. that $q' > p'$ holds, we have that the last sum is convergent in $t$. We denote the limit of that series just by $B$ and can proceed with:

- $\mathbb{P}(q(t) > b) \leq e^{-\theta t + \theta q t} \sum_{s=0}^{t} e^{\rho U(s, t)} (1 - s) + \theta q (\mathbb{E}(e^{\theta q U(s, t)}) + \mathbb{E}(\theta q U(s, t)))^{1/q}$

The above sum, however, does in general not converge. This is due to the three inequalities:

- $\rho U(s, t) \geq \rho(t) \forall t \geq 1$,
- $\rho(t) \geq -\rho(t) \forall t \geq 0$,
- $-\rho(t) \geq -\rho(t) \forall q \geq 1$.

For the case $q' = p' = 2$, the exponents in the last sum vanish and the expression reduces to $t - s + 1 \leq e^{\theta t - s}$, such that the bound becomes:

- $\mathbb{P}(q(t) > b) \leq e^{-\theta t + 2\rho(t)} \sum_{s=0}^{t} e^{\rho(t) + 2\rho(t)} = e^{-\theta t + 2\rho(t)} \frac{1}{2\rho(t)}$.

Note that the system $U' \rightarrow U \rightarrow U$ is unstable (the concatenation of the two servers with service $U \otimes U$ is at most as large as the arrivals $U$), which is why the above bound is valid only for any finite time $t$.

Overall, we can summarize our findings in the main result of this paper:

**Theorem 10.** Consider a WFC system as in Figure 1 with the placeholder being a dynamic $U$-server.
Let \( \frac{1}{\lambda} + \frac{1}{\lambda'} = \frac{1}{\lambda} + \frac{1}{\lambda'} = 1 \) and \( q' > p' \). Assume the following MGF-bounds on \( U \otimes V \):

\[
\mathbb{E}(e^{\theta s U + V (s,t)}) \leq e^{\theta p(t-s) + \sigma(s)}
\]

\[
\mathbb{E}(e^{\theta s U + V (s,t)}) \leq e^{\theta p(t-s) + \sigma(t-s)}.
\]

The whole system fulfills the probabilistic delay-bound:

\[
P(d_{sys}(t) > x) \leq \mathbb{P}(d_{U \otimes V}(t) > x)
\]

\[
e^{-\sigma_{\text{min}}(t+T) + \sigma} \sum_{i=0}^{T} e^{\theta p(t-i)} B
\]

where

\[
\sigma_E(\theta, p, p') = \pi(p\theta) + \pi(qp\theta) + \pi(qq\theta)
\]

\[
\rho_E(\theta, p, p') = \begin{cases} 
\rho(p\theta) + \rho(qp\theta) & \text{if } p' \neq 2 \\
\rho(p\theta) + \rho(2q\theta) + \frac{1}{\sqrt[p']{q}} & \text{if } p' = 2
\end{cases}
\]

\[
B = \begin{cases} 
\left(1 - e^{\theta p(t-i)} - \rho(pq\theta)\right)^{1/4} & \text{if } p' \neq 2 \\
1 & \text{if } p' = 2
\end{cases}
\]

and \( d_{U \otimes V} \) being the delay of an unthrottled tandem consisting of a dynamic \( U \)- and \( V \)-server.

We want to emphasize that with this theorem it is for first time possible to analyse a general WFC system in the context of SNC. Our solution does not rely on the subadditivity of \( U \) or \( V \) directly, in contrast to what was presented in Section 3 and [3]. Instead we ask for the probability of failing the subadditivity by at least the window size \( \Sigma \), which allows an analysis of general service elements inside the feedback loop. Note that \( U \) and \( V \) do not need to be single service elements themselves, they could instead result from Theorem 3 or include further elements (like fixed delay-elements or scaling elements [10]).

**Remark 11.** It is interesting to note, that, if \( U \otimes V \) is subadditive already, we have \( \mathbb{P}(-E) = 0 \) and the whole system’s service reduces immediately to

\[
U_{sys}(s,t) = U(s,t) \wedge U \otimes V(s,t) = \Sigma_{\text{min}}(t).
\]

One can directly apply Theorem 7 on \( U_{sys} \) to achieve an end-to-end delay bound in this case. Further, we observe that step (13) is not a necessary one. We could, for example, shift \( b \) below \( \Sigma_{\text{min}}(t) \) and continue directly with:

\[
U_{sys}(s,t) \geq U(s,t) \wedge U \otimes V(s,t) = \Sigma_{\text{min}}(t) - b.
\]

We can then apply Theorem 10 on this \( U_{sys} \) (which is at least as large as \( U \otimes V \)). One can view this as a shift in the violation probabilities towards the subadditive part (event \( E \)) of the bound. We investigate this tradeoff in the following section.

**5. NUMERICAL EVALUATION**

In this section, we investigate how the bound derived in Theorem 10 evolves in its parameters. Further, we quantify the impact of WFC on the delay of the system, by comparing it to a similar unthrottled system. For this section we assume \( U \) to be a constant rate server \( U(s,t) = u(t-s) \), which also serves a crossflow \( A_U(s,t) \) at higher priority than \( B \). A well-known result in SNC states that \( B \) receives a service \( U(s,t) = w(t-s) - A_U(s,t) \). Similarly, we insert for the placeholder in Figure 1 a service element \( V \), which also offers a constant rate \( V(s,t) = v(t-s) \) shared with a higher priority crossflow \( A_V(s,t) \), such that \( V(s,t) = v(t-s) - A_V(s,t) \). Note that both service descriptions are subadditive by themselves, but when applying Theorem 3 this property is lost.

To account for the typically smaller size of acknowledgments flowing back to the throttle, we assume \( v > u \). The crossflows in this example consist of i.i.d. exponentially distributed increments \( av(t) \) and \( av(t) \), respectively. The arrivals to the WFC system, denoted by \( A \) also consist of i.i.d. exponentially distributed increments. All flows are stochastically independent of each other. More sophisticated cross-flows or arrivals are possible to analyse, as well as dropping the independency assumption, yet this is not the focus of our evaluation. We further assume a constant window-size \( \Sigma \), for all times \( t \geq 0 \).

A corresponding unthrottled system would just consist of the flow \( A \) being fed into the service element \( U \), thus Theorem 7 could be applied directly.

To achieve reasonable values in the bounds of Theorem 7 and Theorem 10, we numerically optimized the parameter \( \theta \) and the Hölder-pairs \( p, q, p', q' \). If not specified otherwise we used the following set of parameters in our calculations: the bound is taken at time \( t = 5 \) and asks for a delay \( T = 10 \), i.e., we consider the probability \( \mathbb{P}(d_{sys}(5) \geq 10) \). The parameter of the exponential distributions for the arrivals and cross-flows is given by \( \lambda = 4 \) (we assume all three flows to have the same rate \( \lambda \) for simplicity), while the server-rates are \( u = 1 \) and \( v = 2 \). This corresponds to a utilization of 50% and 25%, respectively. We present the results for a window size of \( \Sigma = 15 \).

**5.1 Throttled vs. Unthrottled System**

First we want to compare the system to its unthrottled counterpart. To that end, we alter the arrival rates \( \lambda \), resulting in utilizations from 30% to 80%. We plot the corresponding violation probabilities for the performance bounds on a logarithmic scale for the throttled, as well as the unthrottled system. We did this for different window-sizes \( \Sigma = 10, 15, 20 \). The results are displayed in Figure 2 as black and blue lines for the throttled and unthrottled system, respectively. As expected, the throttled system behaves better, the larger \( \Sigma \) is; for \( \Sigma = 20 \) the throttled system behaves almost identically to the unthrottled one.

**5.2 Dependence on Delay**

A major difference between the unthrottled and the throttled analysis lies in the dependency on the delay \( T \). While for the unthrottled system an increase in \( T \) leads to a decrease in the violation probability, we see in the bound of Theorem 10, that the term \( \mathbb{P}(-E) \) increases in \( T \). In Figure 3, one sees for the black line how the bound evolves for an increasing \( T \). The two red lines show how the bound differs when choosing \( b = \frac{2}{T} \) and \( \frac{2\Sigma}{T} \) as suggested in Remark 11 (Equation (15)). The trend here for larger \( T \) is, that the bound becomes worse, the larger the difference between \( b \) and \( \Sigma \) is. However, for small values of \( T \) there is a very slight improvement for \( b = \frac{2\Sigma}{T} \) and even for \( b = \frac{2}{T} \). In this
Figure 2: A graph showing the violation probabilities depending on the utilization of throttled (black) and unthrottled (blue) systems for different window sizes. The red lines are equal to $10^{-3}$ and $10^{-6}$.

Figure 3: A graph showing how the bound evolves when increasing the delay $T$. The red colored lines represent a shift towards the violation probability of event $E$.

scenario, trading a higher violation probability for the event $E$ is not worthwhile the gain from a better service description $U_{sys}$.

To investigate the composition of the delay bound further, we separated the two parts of the bound in Figure 4. The blue circles correspond to the delay-part of the violation probability $P(d_{v\otimes v}(t) > x)$ and the red circles correspond to the violation probability of event $E$, while the solid black circles are the sum of both. It can be clearly observed that from a certain point onwards the probability $P(\neg E)$ dominates the overall violation probability. The additional lines drawn into the graph show how the different parts of the bound are affected when we use $b = \frac{2}{3}$, $\frac{3}{4}$, $\frac{5}{6}$ in Equation (15). It can be seen that the delay-part (blue) of the probability experiences no considerable change, while the probability of violating event $E$ (red) increases significantly, when $b < \Sigma$.

Figure 4: A graph showing the different components of the violation probability: the blue circles are the delay-part, while the red circles represent the subadditivity-part. The black circles are the sum of both parts. The lines show the same for different shifts towards the violation probability $P(\neg E)$.

5.3 Convergence to Unthrottled System
In Figure 5, we consider the convergence of the throttled system towards the unthrottled one when increasing the window size. Clearly, from Theorem 10 the violation probability $P(\neg E)$ vanishes for increasing window sizes. However, the throttled system does not fully converge to the unthrottled one, since the delay-part of the bound still differs:

$$P(d_{v}(t) > T) \leq P(d_{v\otimes v}(t) > T).$$

The size of the gap, which cannot be closed by increasing the window size further is completely dependent on the service descriptions $U$ and $V$. We present in the graph the same system as before, but vary $v = 2, 1.5, 1.1$. One can see clearly how the gap to the delay of the unthrottled system (red) increases, when reducing the rate of $v$.

6. CONCLUSION AND OUTLOOK
In this paper, we have dealt with the long-standing problem of analysing WFC systems in SNC. While such feedback loops had been solved in deterministic network calculus more than a decade ago, its counterpart in the stochastic setting has been a well-known open problem [15, 12, 13, 8]. We presented how far subadditive service carries DNC solutions for WFC systems into stochastic network calculus (see also [3]). In that discussion, we encountered the very general notion of $\sigma$-additive operators and saw as a tractable example a feedback-loop containing a single subadditive server. Unfortunately, this method reaches the end of the road as soon as operators appear which no longer commute, or are not idempotent. This is not untypical in applications, for example if tandems of servers are involved.

Therefore, we approached subadditivity in a different way and hence, for the first time, successfully analysed general WFC systems in the context of SNC. Instead of assuming subadditive service elements, we leverage the stochastic nature of the problem and ask for the probability of the feedback loop not being subadditive. This effectively allows the
The analysis of WFC systems in MGF-based network calculus. The resulting bounds consist of two parts: first, a delay-bound of a conventional unthrottled system, containing the feedback loop as service; second, a probability of violating the subadditivity, by more than the window size. The structure of our result makes a direct comparison between throttled and unthrottled systems possible.

The analysis of WFC systems in stochastic network calculus is not completed yet, but has rather just begun. While the now available methods can handle varying window sizes $\Sigma$, they can take only limited advantage of their variations. The presented method uses a backlog bound for the system $U \rightarrow U \otimes U \rightarrow \Sigma$. The "arrivals" and "service" in this scenario are strongly correlated. While using Hölder’s inequality deals correctly with that dependence, it also neglects its possible advantages. As the arrivals and the service in this system are positively correlated one can hope to improve the bounds significantly, when taking the dependencies into account.

Besides improving bounds in the above sense, one can extend and build upon this work: one direction is to break the "end-to-end" feedback-loop into several hops, resulting in a tandem of WFC systems. Another interesting question would be how to effectively handle stochastic dependencies between the "upstream"-service $U$, the "down-stream"-elements and the window-process $\Sigma$. Answering this will push the applicability of SNC even further. By better grasping the occurring dependencies one can eventually aim at analysing systems like the window-controlled TCP in SNC.
