Abstract—In this paper, we investigate the stability of a cognitive radio network. We propose a cooperative secondary transmitter-receiver system (CSTR), where, the secondary transmitter (ST) and the secondary receiver (SR) increase the spectrum availability for the ST packets by relaying the unsuccessfully transmitted packets of the primary transmitter (PT). We assume that the cognitive user transmitter will be allowed to use the spectrum holes until they all being emptied. Afterwards, the CR user senses the primary bands and sends a packet from the relaying queues until they all being emptied. In this work, we propose a new cognitive system with the concept of cooperation. In the cooperative secondary transmitter-receiver system (CSTR), the cognitive system with its transmitter-receiver pair tries to utilize the periods of silence of the PT in order to increase the reliability of communication against the effect of random channel variation, i.e., channel fading, and to allow the ST to utilize the channel efficiently and effectively. More specifically, when the secondary transmitter and receiver sense the channel for empty time slots, the slots are then used to help the primary system, and/or to allow the ST’s packets to be served.

We make the following contributions in this paper.

- We propose a new cooperative system (CSTR), where both the secondary transmitter and receiver are used as relays for the primary terminal.
- We design a new protocol to manage the undelivered packets decoding at the terminals and the channel.

Mohammed Nafie is also affiliated with the Electronics and Communication Engineering, Nile University, Egypt.

Index Terms—Cognitive radio, closure, stability analysis.
to sense the channel every time slot to check whether the PT is idle or not. The cognitive system will be able to send a packet each time slot during the idle sessions of the PT. The main assumptions of the system model at both the MAC and physical (PHY) layers are discussed in this section.

A. PHY Layer Assumptions

Denote the primary source as ‘ps’, the primary destination as ‘pd’, the secondary source as ‘ss’, and the secondary destination as ‘sd’. Let \( h_{j,k}^t \) denote the channel gain between node \( j \) and node \( k \) at instant \( t \), where \( j, k \in \{ss, sd, ps, pd\} \), and it is distributed according to a zero mean circularly symmetric complex Gaussian random variable with variance \( \sigma^2_{j,k} \), i.e., \( \mathcal{CN}(0, \sigma^2_{j,k}) \). Channel gains are independent and each link is perturbed by complex additive white Gaussian noise (AWGN) with zero mean and with variance \( \mathcal{N}_o \) and independent for all links. In this paper, we consider MPR channel model which can capture the effect of interference and fading at the PHY layer. Packets could survive the interference caused by concurrent transmissions if the received signal-to-interference and noise ratio (SINR) exceeds the threshold required for successful decoding at the receiver, i.e., for the link between node \( j \) and node \( k \) the probability of successful reception of the packet from node \( j \) at its receiving node \( k \) when there is a concurrent transmission from node \( \ell \) is given by

\[
\Pr(O_{j,k}) = \Pr[(\text{s} | P_{j,k} \leq \text{SNR}_t)] = 1 - \exp\left(-\frac{\gamma_{th,k}N_o}{\sigma^2_{j,k}P_{j,k}}\right)
\]

where \( P_{j,k} \) denotes the transmission power of node \( j \) and \( O_{j,k} \) is the event that the link between node \( j \) and node \( k \) is in outage. The SNR threshold \( \gamma_{th,k} \) is a function of different factors in the communication system; it is a function of the application, the modulation, the signal processing applied at encoder/decoder sides, error-correction codes, and many other parameters [10].

From the Appendix, the probability of packet correct reception of a transmitted packet from node \( j \) to node \( k \) when there is a concurrent transmission from node \( \ell \) is given by

\[
\Pr_{j,k} = \frac{1}{1 + \frac{\gamma_{th,j,k}N_o}{\sigma^2_{j,k}P_{j,k}}} \Pr_{j,k}
\]

B. MAC Layer Assumptions

We assume that the PT has a buffer \( Q_p \) to store the incoming traffic packets, while the ST has two buffers, \( Q_s \) to store its own arriving traffic packets and \( Q_{ps} \) to store a fraction of undelivered packets of the PT. We assume all buffers are of infinite length. We consider time-slotted transmission where all packets have the same size and one time slot is sufficient for the transmission of a single packet. The arrival processes

...
to the primary and the secondary queues are assumed to be independent Bernoulli processes with mean arrival rates $\lambda_p \in [0, 1]$ and $\lambda_s \in [0, 1]$ packets per time slot, respectively.

In this system, denoted by $S$, the ST accepts a fraction of the undelivered packets of the PT, i.e., it will decide to accept a controllable fraction to be admitted into its relaying queue in case of outage on the primary channel using an adaptive admission control parameter $f_s$, and the SR has a buffer $Q_{sd}$ to store undelivered packets of the PT in order to accept a fraction $f_{sd}$ of the undelivered packets of the PT. We assume that for successfully decoded packets by the ST and the SR, the priority of keeping the packet is one of the optimization parameters of the system defined as a binary value $P$, i.e., $P = 1$ if the priority is assigned to the SR, and $P = 0$ if the priority is assigned to the ST. We assume that the acknowledgment (ACK) and negative-acknowledgement (NACK) messages initiated by the node with the higher priority of keeping are sent earlier than the messages that are sent by the lower priority one, i.e., the node with priority of keeping transmits ACKs and NACKs from $\tau_1$ to $\tau_2$ within the time slot and the other node transmits from $\tau_2$ to $\tau_3$. Note that the primary receiver (PR) sends the feedback messages over the period $\tau_0$ to $\tau_1$.

The MAC layer is assumed to obey the following transmission scheme.

- Assign the priority of keeping the undelivered PT packet to the ST or the SR at the beginning of the transmissions.
- The primary user transmits the packet at the head of its queue. If the queue is empty the time slot is free.
- If a packet is received successfully by either the PR, the ST, or the SR the packet is removed from the PT’s queue (the ST or the SR needs to send an ACK if a packet is not decoded correctly by the PR in this case).
- If both the ST and SR decoded a packet correctly, the terminal which has the priority of keeping, will keep the packet and the packet will be removed from other node’s buffer.
- If a packet is not received successfully by the PR, the ST, and the SR, the PT retransmits this packet in the next time slot.
- The ST and SR randomly access the channel at each sensed empty time slot (ALOHA random access).
- At each sensed empty time slot, the ST transmits a packet from its own queue with probability $p_{sp}$, transmits a packet from the relaying queue with some probability $p_{sp}$, or remains idle with probability $p_s = 1 - p_{sp} - p_{sp}$. The SR attempts to retransmit the undelivered packets of the PT with probability $p_{sd}$, or to remain idle with probability $1 - p_{sd}$.
- Packets could survive the interference caused by concurrent transmissions between the ST and the SR, if the received SINR exceeds the threshold required for successful decoding at the receiver.

We assume that the overhead for transmitting the ACK and NACK messages is very small compared to packet sizes. The second assumption we make is that the errors and delay in packet acknowledgement feedback is negligible, which is reasonable for short length ACK/NACK packets as low rate codes can be employed in the feedback channel [10]. In addition, nodes cannot transmit and receive at the same time which is a common assumption where terminals are equipped with single transceivers [5].

### III. Stability Analysis of the Proposed System

Let us denote the queue sizes of the transmitting terminals at any time instant $t$ by $Q_i^t$, where $i$ reads $p$ for the PT’s queue, $s$ for ST’s queue, $ps$ for the ST’s relaying queue, and $sd$ for the SR’s relaying queue. A fundamental performance measure of a communication network is the stability of its queues. More rigourously, stability can be defined as follows [5], [10].

**Definition:** Queue $Q_i \in \{Q_p, Q_s, Q_{ps}, Q_{sd}\}$ is stable, if

$$\lim_{t \to \infty} Pr\{Q_i^t < y\} = F(y) \text{ and } \lim_{y \to \infty} F(y) = 1. \tag{2}$$

If the arrival and service processes are strictly stationary, then we can apply Loynes’ theorem to check for stability conditions [10], [11]. This theorem states that if the arrival process and the service process of a queue are strictly stationary processes, and the average service rate is greater than the average arrival rate of the queue, then the queue is stable, otherwise the queue is unstable.

The service and arrival rates of the nodes are as follows. For terminal $i = p$, given that the priority factor $P = 1$, i.e., the priority of keeping the packet is assigned to the SR, a packet can be served if either one of the four events is true: 1) The primary channel is in outage, the SR decides to accept the packet (with probability $f_{sd}$), and the channel $h_{ps, sd}$ is not in outage; 2) the primary channel is in outage, the ST decides to accept the packet (which happens with probability $f_s$) and the SR decides not to accept the packet (which happens with probability $1 - f_s$), and the associated link $h_{ps}$ is not in outage; 3) the primary channel is in outage, the ST and receiver both of them decide to accept the primary packet and both of them decode it correctly; or 4) if the channel between the primary source and PR is not in outage, i.e., $O_{ps, pd}$ is true. Due to the stationarity assumption of the channels gain, and using the outage probability formula (1), the probability of the event $O_{ps, pd}^c$ is given by $P_t(O_{ps, pd}^c) = P_{ps, pd}$. From the aforementioned argument, it is clear that the queue service process is stationary process and has a finite mean:

$$\mu_p = P_{ps, pd} + P_{ps, pd} \left[ f_{sd} P_{ps, sd} + (1 - f_{sd}) P_{ps, sd} \right] f_s F_{ps, ss}. \tag{3}$$

According to Loynes theorem, the stability condition of the queue $Q_i$ is given by

$$\mu_i > \lambda_i. \tag{4}$$
If we take the priority of keeping factor into account, the general formula of the average service rate of the PT is given by

$$\mu_p = P_{ps, pd} + P_{ps, pd} \left[ \mathcal{P} \left( f_{sd} ^ {T_{ps, sd}} + (1 - f_{sd} ^ {T_{ps, sd}}) f_s ^ {T_{ps, ss}} \right) + f_s ^ {T_{ps, ss}} \left( 1 - f_{sd} ^ {T_{ps, ss}} \right) \right].$$

$$\mu_p = P_{ps, pd} + P_{ps, pd} \left[ f_{sd} ^ {T_{ps, sd}} + f_s ^ {T_{ps, ss}} - f_s ^ {T_{ps, ss}} f_{sd} ^ {T_{ps, ss}} \right].$$

(5)

It should be mentioned that $\mu_p$ is independent of $\mathcal{P}$. Given that, the primary queue is empty, the ST assigns the channel to its own queue (which happens with probability $P_{ps}$), and the channel between the ST and its respective receiver is not in outage, a packet in $Q_s$ is served if the ST decides to access the channel with the relaying queue (which happen with probability $P_{ss}$), or if the SR queue is empty. The probability that the primary terminal queue is empty is given by [10]

$$\Pr \{ Q_{ps}^t = 0 \} = 1 - \frac{\lambda_p}{\mu_p}. \quad (6)$$

From the above argument and the expression given in (6), the mean service rate of the ST own data queue, $Q_{ss}$, is given by

$$\mu_{ss} = \left( 1 - \frac{\lambda_p}{\mu_p} \right) T_{ss, pd} P_{s} \left[ \Pr \{ Q_{ss}^t = 0 \} + T_{ss, pd} P_{s} \Pr \{ Q_{ss}^t \neq 0 \} \right].$$

(7)

Consider now the relaying queue of the ST, $Q_{ps}$. Given that the queue of the PT is empty in a time slot $t$ and the ST chooses to access the channel with the relaying queue (which happens with probability $P_{ps}$), a packet from queue $Q_{ss}$ can be served in either one of the three following events: 1) If the ST is idle, and the channel between the ST and the PR is not in outage $T_{ss, pd}$; 2) if the ST does not access the channel (which happens with probability $P_{ss, pd}$), and its queue is not empty, i.e., $Q_{ss}^t \neq 0$, and the channel between the ST and the PR is not in outage; or 3) if the queue $Q_{ps}$ in time slot $t$ is not empty, the ST accesses the channel (which happens with probability $P_{ps}$), and the complement of the event outage between the ST and the PR $T_{ss, ps} | T_{ss}$, where $T_{ss, ps} | T_{ss}$ denotes the complement of the outage event between node $j$ and node $k$ when there is a concurrent transmission by node $\ell$. The expected value of the service process of the relaying queue $Q_{ps}$ is given by

$$\mu_{ps} = \left[ \Pr \{ Q_{ps}^t = 0 \} + P_{ps} \Pr \{ Q_{ps}^t \neq 0 \} \right] T_{ps, pd}$$

$$\mu_{ps} = \left( 1 - \frac{\lambda_p}{\mu_p} \right) P_{ps, pd} \left[ \Pr \{ Q_{ps}^t = 0 \} + P_{ps} \Pr \{ Q_{ps}^t \neq 0 \} \right].$$

(8)

Consider now the SR queue $Q_{sd}$. Given that the queue of the PT is empty in time slot $t$, a packet from queue $Q_{sd}$ can be served if in a time slot $t$ in either one of the six following events: 1) If the SR decides to access the channel (which occur with probability $P_{sd}$), the ST has no packets in any of its queues, i.e., $Q_{ps}^t = 0$ and $Q_{ss}^t = 0$, and the complement of the event outage between the SR and the PR $T_{sd, ps}$; 2) if the SR decides to access the channel, the event that the ST’s queues are $Q_{ps}^t \neq 0$ and $Q_{ss}^t = 0$ and it does not access the channel (which happens with probability $P_{sp}$), and the complement of the event outage between the SR and the PR $T_{sd, ps}$; 3) if the SR decides to access the channel, the event that the ST’s queues are $Q_{ps}^t = 0$ and $Q_{ss}^t \neq 0$ and it does not access the channel (which happens with probability $P_{sp}$), and the complement of the event outage between the SR and the PR $T_{sd, ps}$; 4) if the SR decides to access the channel, the event that the ST’s queue is empty in either one of the three following events: 1) If the SR decides to access the channel, the event that the queue $Q_{ps}^t \neq 0$ and $Q_{ss}^t = 0$, and the complement of the event outage between the SR and the PR $T_{sd, ps}$; or 6) if the SR decides to access the channel, the event that the queue $Q_{ps}^t \neq 0$ and the ST accesses the channel (with probability $P_{ps}$), and the complement of the outage event between the SR and the PR given a transmission between the ST and the PR $T_{sd, ps}$; 5) if the SR decides to access the channel, the event that the queue $Q_{ps}^t = 0$ and the ST accesses the channel (with probability $P_{ps}$), and the complement of the outage event between the SR and the PR given a transmission between the ST and the PR $T_{sd, ps}$ $T_{ps}$

$$\begin{align*}
\lambda_{ps} &= \frac{\lambda_p}{\mu_p} P_{ps, pd} \left( 1 - f_{sd} ^ {T_{ps, sd}} \right) f_s ^ {T_{ps, ss}}.
\end{align*}$$

(10)

Adding the keeping priority factor, the mean arrival rate of the queue $Q_{ps}$ is then given by

$$\lambda_{ps} = \frac{\lambda_p}{\mu_p} P_{ps, pd} \left( 1 - f_{sd} ^ {T_{ps, sd}} \right) f_s ^ {T_{ps, ss}}.$$

(11)

The arrival process to $Q_{sd}$ can be described as follows. The event that the primary has packets, i.e., $Q_{ps}^t > 0$, the SR decides to accept a packet from the PT $W_{sd}$, the channel between the PT and the SR is connected, and the associated
channel to the primary terminal-PR is in outage. The process can be modeled as

$$A_{sd}' = \left[ W_{sd} \cap \{ Q_p > 0 \} \right] \cap A_{ps,pd} \cap A_{ps,sd}. \quad (12)$$

The process is stationary and the expected value of the arrival process to the queue $Q_{sd}$ is expressed as

$$\lambda_{sd} = f_{sd} P_{ps,pd} \frac{\lambda_p}{\mu_p} \lambda_{ps}, \quad (13)$$

If we involve $\mathcal{P}$, the mean arrival rate of the SR queue is given by

$$\lambda_{sd} = \frac{\lambda_p}{\mu_p} P_{ps,pd} \left( 1 - P_{ps,sd} \right) f_{sd} P_{ps,sd}. \quad (14)$$

Since the mean service rates at nodes $s$, $ps$ and $sd$ depend on each other queue size, these queues are called interacting queues, and consequently the rates of the individual departure processes cannot be computed directly. In order to overcome this problem, we utilize the idea of stochastic dominance, which has been applied before to analyze interacting queues in Aloha systems [5], [10], [12], [13], to obtain inner bounds on the stability region. For the outer bounds, we upper bound the queues service rates such that the service rates of the queues become decoupled.

### A. CSTR: Inner Bound

The inner bound is the union over two inner bounds based on two dominant systems.

1) **First Dominant System**: In this system designated as $S_1$, $Q_{sd}$ and $Q_{ps}$ send dummy packets when their queues are empty, and the $Q_{ps}$ behaves exactly as it would in the original system $S$. Now, we can write down the service and arrival rates of the interacting queues, i.e., $Q_s$, $Q_{ps}$ and $Q_{sd}$ as follows. The mean service rates of $Q_{sd}$ and $Q_{ps}$ are given by

$$\mu_{sd} = (1 - \frac{\lambda_p}{\mu_p}) (1 - P_{sd,ss}) \mu_{ps}, \quad (15)$$

$$\mu_{ps} = (1 - \frac{\lambda_p}{\mu_p}) P_{sp} \left[ P_{ps,ss} + P_{sd,ss} \right]. \quad (16)$$

The probability $Pr\{Q_{ps} = 0\}$ is given by

$$Pr\{Q_{ps} = 0\} = 1 - \frac{\lambda_{ps}}{\mu_{ps}} \quad (17)$$

Therefore,

$$\mu_{sd} = (1 - \frac{\lambda_p}{\mu_p}) P_{sd} \left[ \left( 1 - \frac{\lambda_{ps}}{\mu_{ps}} \right) \mu_{ps} P_{ps,ss} + \left( \frac{\lambda_{ps}}{\mu_{ps}} + \lambda_{sd} \right) P_{sd,ss} \right]. \quad (18)$$

According to the construction of the dominant system $S_1$, it is easy to see that the queues of the dominant system are never less than those of the original system, provided they are both initialized identically (with the same initial conditions for queue sizes in both the original and dominant system). This is because, in the dominant system $S_1$, the SR transmits dummy packets even if it does not have any packets in its queue, and therefore interferes with ST in all cases that it would in the original system. Therefore, if the queues at all nodes are stable in the dominant system, then the corresponding queues in the original system must be stable. The first inner bound $R(S_1)$ which is based on $S_1$ is given by the closure of the rate pairs $(\lambda_p, \lambda_s)$ constrained by equations shown above as $f_s, f_{sd}, p_s, p_{ps}$, and $P_{sd}$ vary over $[0,1]$, and $\mathcal{P}$ varies over $\{0,1\}$ [5], [13]. For a fixed $\lambda_p$, the maximum stable arrival rate to the ST’s queue is given by the following optimization problem (as in [5], [10]):

$$\begin{align*}
\max_{P_{ps,pd},f_{sd}} & \lambda_s = \lambda_s \\
\text{s.t.} & \begin{cases} 0 \leq P_{ps}, P_{pd}, f_{sd}, f_s, f_{sd} \leq 1, \\ P \in \{0,1\}, \\ p_s + p_{ps} \leq 1 \\ \lambda_p \leq \mu_p, \quad \lambda_{ps} \leq \mu_{ps}, \quad \lambda_s \leq \mu_s. \end{cases} \quad (19)
\end{align*}$$

2) **Second Dominant System**: The second dominant system is designated as $S_2$, where the ST is the one that sends dummy packets from $Q_p$ and $Q_{ps}$, i.e., $Pr\{Q_{sd} = 0\} = Pr\{Q_{ps} = 0\} = 0$, and the SR behaves exactly as it would in the original system $S$. The mean service rate of $Q_{sd}$ is given by

$$\mu_{sd} = (1 - \frac{\lambda_p}{\mu_p}) P_{sd} \left[ P_{ps,ss,ps} + (p_{pd} + p_s) P_{sd,ss,ps} \right]. \quad (20)$$

The probability that $Q_{sd}$ is empty is given by

$$Pr\{Q_{sd} = 0\} = 1 - \frac{\lambda_{sd}}{\mu_{sd}} \quad (21)$$

Thus, the mean service rate of the ST’s queues are given by

$$\mu_s = (1 - \frac{\lambda_p}{\mu_p}) \left[ P_{ss,ss} P_{ss,ps} + P_{ps,ss} P_{pd,ss,ps} \right]. \quad (22)$$

$$\mu_{ps} = (1 - \frac{\lambda_p}{\mu_p}) P_{sp} \left[ (1 - P_{sd,ss}) \mu_{ps} P_{ps,ss} + P_{sd,ss} \mu_{sd} P_{sd,ss,ps} \right]. \quad (23)$$

The second inner bound for the stable-throughput region of the CSTR system, $R(S_2)$, which is based on the dominant system $S_2$, can be obtained by formulating a constrained optimization problem similar to that discussed above for the first dominant system, where we fix $\lambda_p$ and maximize $\lambda_s$ as $f_s, f_{ps}, p_s, p_{ps}$, and $P_{sd}$ vary over $[0,1]$ and $\mathcal{P}$ varies over $\{0,1\}$.

### B. CSTR: Outer Bound

Here we provide two outer bounds for CSTR.

1) **First Outer Bound**: The first outer bound for the CSTR, denoted by $S_{1}^{(o)}$, can be obtained by upper bounding the joint probability identities and using Bayes’ theorem [7]. More specifically,

$$Pr\{Q_{sd} = 0\} + P_{sd} Pr\{Q_{sd} \neq 0\} \leq Pr\{Q'_{sd} = 0\} + Pr\{Q'_{sd} \neq 0\} = 1, \quad (23)$$

\[\text{6}\text{The optimization problems of the first and second dominant systems are solved numerically using Matlab optimization toolbox. Since the problems are nonconvex, the solver produces a locally optimum solution. To increase the likelihood of obtaining the global optimum, the program is run many times, say 10000 times, with different initializations of the optimization variables.}\]
and
\[
\left( \Pr Q_{sd}^t = 0 \right) \Pr \{ Q_{sd}^t \neq 0 \} \Phi_{ss,ps,dd} \quad + \quad p_{sd} \Pr \{ Q_{sd}^t \neq 0 \} \Phi_{ss,ps,dd} \leq \Phi_{ss,ps,dd}.
\]

Based on Bayes’ theorem, we have
\[
\Pr \{ a, b \} = \Pr \{ a \} \Pr \{ b \} \quad \text{or} \quad \Pr \{ a, b \} = \Pr \{ b \} \Pr \{ a \} \leq \Pr \{ a \}
\]
where \( a \) and \( b \) are any two arbitrary events. We can upper bound the following quantities in formula (9):
\[
\begin{align*}
\Pr \{ Q_{ps}^t = 0, Q_{sd}^t = 0 \} & \leq \Pr \{ Q_{ps}^t = 0 \}, \\
\Pr \{ Q_{ps}^t \neq 0, Q_{sd}^t = 0 \} & \leq \Pr \{ Q_{ps}^t \neq 0 \}, \\
\Pr \{ Q_{ps}^t = 0, Q_{sd}^t \neq 0 \} & \leq \Pr \{ Q_{ps}^t = 0 \}, \\
\Pr \{ Q_{ps}^t \neq 0, Q_{sd}^t \neq 0 \} & \leq \Pr \{ Q_{ps}^t \neq 0 \}.
\end{align*}
\]

Based on the above facts, the mean service rates of the ST’s queues can be upper bounded as follows:
\[
\mu_s \leq \left( 1 - \frac{\lambda_p}{\mu_p} \right) \Phi_{ss,ps,dd} \mu_s \leq \left( 1 - \frac{\lambda_p}{\mu_p} \right) p_{sd} \Phi_{ss,ps,dd}.
\]

Therefore, the mean service rate of \( Q_{sd} \) is upper bounded as follows:
\[
\mu_{sd} \leq \left( 1 - \frac{\lambda_p}{\mu_p} \right) p_{sd} \phi \left( 1 - \frac{\lambda_p}{\mu_p} \right) p_{sd} \Phi_{ss,ps,dd}.
\]

When the inequalities hold, the queues are not interacting anymore and therefore we can obtain the outer bound by solving a constrained optimization problem to get the closure (\( \lambda_p, \lambda_s \)). The optimization problem is similar to (19).

2) Second Outer Bound: Another outer bound which can be stated analytically is obtained as follows. Using (5):
\[
\mu_p = P_{ps,dd} + P_{ps,dd} f_s \Phi_{ps,dd} \quad \text{and} \quad \mu_s = \left( 1 - \frac{\lambda_p}{\mu_p} \right) p_{sd} \Phi_{ss,ps,dd}.
\]

Then the inequality (28) holds and applying Loynes’ law
\[
\lambda_s \leq \mu_s \leq \left( 1 - \frac{\lambda_p}{\mu_p} \right) \Phi_{ss,ps,dd}.
\]

Denote the second outer bound as \( S_2^{\text{o}} \). The outer bound can be characterized by the rate pairs
\[
\mathcal{R}(S_2^{\text{o}}) = \left\{ (\lambda_p, \lambda_s) : \frac{\lambda_p}{\Phi_{ss,ps,dd}} + \frac{\lambda_p}{1 - P_{ps,dd} P_{ps,dd} P_{ps,ss}} < 1 \right\}.
\]

The outer bound, \( S^{\text{o}} \), of the CSTR is the intersection of the two outer bounds, i.e., \( \mathcal{R}(S^{\text{o}}) = \mathcal{R}(S_1^{\text{o}}) \cap \mathcal{R}(S_2^{\text{o}}) \). Note that since the service rates of the queues in \( S_1^{\text{o}} \) are upper bounded to obtain the mean service rates of the queues in \( S_2^{\text{o}} \) (see (28) to (30)), therefore, \( \mathcal{R}(S_1^{\text{o}}) \) is contained inside \( \mathcal{R}(S_2^{\text{o}}) \), i.e., \( \mathcal{R}(S_1^{\text{o}}) \cap \mathcal{R}(S_2^{\text{o}}) = \mathcal{R}(S_1^{\text{o}}) \).

IV. NUMERICAL RESULTS

In this section we provide the solution of the optimization problems considered in this paper. The inner (the union of the dominant systems stability regions) and the outer (intersection of the proposed outer bounds) bounds of the CSTR are depicted in Fig. 2. The parameters used to generate the figure are: \( P_{ps,dd} = 0.2, P_{ss,ss} = 0.2, P_{ps,ss} = 0.08, P_{ss,ps} = 0.08, P_{sd,ps} = 0.02, P_{ps,ss} = 0.02, P_{ss,ps} = 0.54, \) and \( P_{ps,ss} = 0.51 \). It can be seen that the inner and outer bounds almost overlap for the parameters used. This might indicate that the bounds are tight.

A comparison between the proposed system, NCPQ and NCNPQ is depicted in Fig. 3. The parameters used to generate this figure are: \( P_{ps,dd} = 0.4, P_{ss,ss} = 0.2, P_{ps,ss} = 0.08, P_{ss,ps} = 0.08, P_{sd,ps} = 0.02, P_{ps,ss} = 0.02, P_{ss,ps} = 0.54, \) and \( P_{ps,ss} = 0.51 \). Note that NCPQ and NCNPQ are coincide for the used parameters. It should be mentioned that if the link of the primary is always in outage with probability 1, i.e., there is no direct link between the PT and PR (the PT’s packets will never be served if there is no cooperation, i.e., \( \mu_p = \Phi_{ps,dd} = 0 \)), the CSTR performance will significantly overcome the maximum stable throughput of (NCPQ) and (NCNPQ) as seen in Fig. 4. The parameters used to generate the figure are: \( P_{ps,dd} = 1, P_{ss,ss} = 0.2, P_{ps,ss} = 0.8, P_{ss,ps} = 0.8, P_{sd,ps} = 0.02, P_{ps,ss} = 0.02, P_{ss,ps} = 0.54, \) and \( P_{ps,ss} = 0.51 \).

From the figures, the envelope of the stability is a monotonically decreasing with the mean arrival rate of the PT. \( \lambda_p \). This is because as the primary arrival rate increases the probability of the primary queue to be empty vanishes and the secondary queue will not be able to access the channel. It is also noted that the feasible range of the primary arrival rate expands due to cooperation.

V. CONCLUSION

In this paper, we have addressed the impact of cooperative cognition on the stability region of a network composing of one primary transmitter-receiver pair and one secondary transmitter-receiver pair. We have investigated the maximum stable-throughput of the CSTR. In CSTR, the cognitive transmitter and receiver sense the channel for idle channel resources and exploit them to either relay the undelivered packets of the PT or serve the ST own data traffic. We have provided two inner and outer bounds on the stability region of the network.

APPENDIX

Under Rayleigh fading channels, the outage probability between terminal \( j \) and terminal \( k \) when there is a transmission
caused by node \( i \) [5] is given by

\[
P_{\text{pd}}^{\ell} = \Pr\{O_{j,k} | T_\ell\} = \Pr\left\{ \frac{P_{j}}{|h_{\ell,j,k}|^2 + \lambda} \leq \gamma_{th,k} \right\} = 1 - \frac{1}{1 + \frac{\Pr_{\gamma_{th,k}, \lambda} \sigma_{j,k}}{\sigma_{j,k}}} \exp\left( - \frac{\gamma_{th,k} \lambda}{\sigma_{j,k}} \right).
\]

where \( \{T_\ell\} \) is the event that the terminal \( \ell \) is transmitting a packet. After some mathematical manipulations, it can shown that the probability of correct packet reception in case of interference is given by

\[
P_{\text{cr}}^{j,k} = \frac{1}{1 + \frac{\Pr_{\gamma_{th,k}, \lambda} \sigma_{j,k}}{\sigma_{j,k}}} P_{j,k}.
\]

Fig. 2. Inner and outer bounds for CSTR: \( P_{\text{pd}}^{\text{all}} = 0.2 \), \( P_{\text{ad}}^{\text{all}} = 0.2 \), \( P_{\text{pd}}^{\text{all}} = 0.08 \), \( P_{\text{ad}}^{\text{all}} = 0.08 \), \( P_{\text{pd}}^{\text{all}} = 0.02 \), \( P_{\text{ad}}^{\text{all}} = 0.02 \), \( P_{\text{pd}}^{\text{all}} = 0.54 \), and \( P_{\text{ad}}^{\text{all}} = 0.51 \).

Fig. 3. Comparison between the maximum stable-throughput of the CSTR, NCPQ, NCNPQ, and the no cooperation case: \( P_{\text{pd}}^{\text{all}} = 0.4 \), \( P_{\text{ad}}^{\text{all}} = 0.2 \), \( P_{\text{pd}}^{\text{all}} = 0.08 \), \( P_{\text{ad}}^{\text{all}} = 0.08 \), \( P_{\text{pd}}^{\text{all}} = 0.02 \), \( P_{\text{ad}}^{\text{all}} = 0.02 \), \( P_{\text{pd}}^{\text{all}} = 0.54 \), and \( P_{\text{ad}}^{\text{all}} = 0.51 \). Note that NCPQ and NCNPQ are coincide for the used parameters.

Fig. 4. Worst case comparison between the maximum stable-throughput of the CSTR, NCPQ and NCNPQ systems: \( P_{\text{pd}}^{\text{all}} = 1 \), \( P_{\text{ad}}^{\text{all}} = 0.2 \), \( P_{\text{pd}}^{\text{all}} = 0.8 \), \( P_{\text{ad}}^{\text{all}} = 0.02 \), \( P_{\text{pd}}^{\text{all}} = 0.02 \), and \( P_{\text{ad}}^{\text{all}} = 0.51 \). Note that NCPQ and NCNPQ are coincide for the used parameters. The mean service rate of the primary queue, in case of no cooperation, is zero, i.e., \( P_{\text{pd}}^{\text{all}} = 0 \).
