ABSTRACT

We consider in this paper a set of connections sharing a common bottleneck link. We assume first that we have data transfer using TCP congestion control protocol and realtime traffic using some TCP-friendly transport protocol that satisfies the same square-root formula for throughput. The performance measures are determined according to the operational parameters of a RED buffer management. Those parameters are assumed to be able to give differentiated services to the applications according to their choice of service class. In terms of loss probabilities and of throughputs, we consider a best effort type of service differentiation where the QoS of connections is not guaranteed, but by choosing a better (more expensive) service class, the QoS parameters of a session can be improved (as long as that session is the only one to change its service class). We assume however, that the system is dimensioned so as to satisfy some average delay requirement. The choice of a service class of an application will depend both on the utility as well as on the cost it has to pay. We first study the performance of each traffic source as a function of the connections' parameters and the pricing policy of the network. We then study the Stackelberg equilibrium, i.e. the service provider's problem of how to choose the pricing so as to maximize its utility, taking into account the reaction of the users.

TCP, Buffer Management, RED/AQM, Stackelberg equilibrium, Pricing

1. INTRODUCTION

We study in this paper the performance of competing connections that share a bottleneck link. All connections are assumed to have controlled rates that are "TCP friendly", they satisfy the well known square-root relation bei.e. tween marking probability and throughput [10, 12, 13]. A RED buffer management is used for early drop of packets. We allow for service differentiation between the connections through the packet dropping (or marking) probability which may depend on the connection (or on the connection class). More specifically, we consider a buffer management scheme that uses a single averaged queue length to determine the dropping probabilities (similar to the way it is done in the RIO-C (coupled RIO) buffer management, see [14]); for any given averaged queue size, packets belonging to connections with higher priority have smaller probability of being dropped than those belonging to lower priority classes. We compute the throughput and the average drop probability for each connection. We assume in our model that the average queue size is a predetermined system parameter, i.e. there is a *target value for the average queue length* which implies also a *fixed average queueing delay* at the buffer. Since the throughputs of connections can vary (according to the price they pay), this means that the link rate is adapted to the connections' input rates so as to guarantee this desirable average queue length.

We then address the question of the choice of priorities. Given utilities that depend on the performance measures, on one hand, and on the cost for a given priority (i.e. the pricing strategy of the provider), on the other hand, each user is faced with an optimization problem, which we solve explicitly. This then allows us to determine the choice of pricing strategy by the service provider which maximizes its own

profits; the solution to this bi-level optimization problem is known as the Stackelberg equilibrium. Note that throughout the paper, we use indifferently user or connection (we place ourselves at the transport/flow layer).

In a previous paper [3], we analyzed a related problem with TCP and CBR traffic sharing a common bottleneck buffer without a given target on the average queueing delay. This created a strong coupling between the different connections, so that the utility of a given connection was influenced by the user priority choices of all other connections. This gave rise to a more complicated modeling of the problem faced by the users (for a fixed pricing strategy of the provider) which was shown to be a non-cooperative game. Although some properties of the equilibrium of the game were obtained in [3], we were not able to obtain explicit formulae for the equilibrium priority choices and therefore did not treat the Stackelberg problem there.

Related references. We briefly mention other recent work in that area. Reference [6] has considered a related problem where the traffic generated by each session was modeled as a Poisson process, and the service time was exponentially distributed. The decision variables were the input rates and the performance measure was the goodput (output rates). The paper restricted itself to symmetric flows and symmetric equilibria and the pricing issue was not considered. In this framework, with a common RED buffer, it was shown that an equilibrium does not exist. An equilibrium was obtained and characterized for an alternative buffer management that was proposed, called VLRED. We note that, in contrast to [6], we do obtain an equilibrium when using RED. For other related papers, see for instance [11] (in which a priority game is considered for competing connections sharing a drop-tail buffer), [1] as well as the survey [2]. In [16], the authors present mechanisms (e.g., AIMD of TCP) to control end-user transmission rate into differentiated services Internet through potential functions and corresponding convergence to Nash equilibrium. These references have not studied the Stackelberg equilibrium concept.

Stackelberg equilibrium has been used in other contexts of networking in [4, 9]. Both references consider M/M/1 type models for congestion. In our paper we model both TCP behavior as well as real time traffic, both sharing a common RED type router as a bottleneck. Other Stackelberg games in networking which are not directly related to TCP or to RED are [7, 19].

The structure of this paper is as follows. In Section 2 we describe the model of RED, then in Section 3 we compute the throughputs and the loss probabilities of the connections for given priorities chosen by the connections. In Section 4 we obtain the optimal priority choices of the connections for given pricing strategies of the network. The optimal pricing is then discussed in Section 5.

2. THE MODEL

RED is based on the following idea: there are two thresholds q_{\min} and q_{\max} such that the drop probability is 0 if the average queue length q is less than q_{\min} , 1 if it is above q_{\max} , and $p_{\max}(q-q_{\min})/(q_{\max}-q_{\min})$ if it is q with $q_{\min} < q < q_{\max}$; the latter is the congestion avoidance mode of operation. This is illustrated in Figure 1. p_{\max} is the maximum loss probability in the congestion avoidance mode of operation.

Figure 1: Drop probability in RED as function q

We consider a set \mathcal{N} containing N TCP flows (or TCP friendly flows) for data transfer and a set \mathcal{I} containing I real time flows, assumed to be TCP friendly (in the sense that they are rate controlled according so as to achieve the same throughput that TCP achieves as a function of loss probabilities and round trip time, see eq. (1)). We assume that connections can be differentiated by means of RED algorithm; they all share a common buffer yet RED treats them differently¹. We assume that they all have common values of q_{\min} and q_{\max} but each flow i may have a different value of $p_{\max}(i)$, which is the value of the drop probability as the average queue tends to q_{\max} (from the left), see Figure 1. Denote $\mathbf{p} = \{p_{\max}(i), i \in \mathcal{I} \cup \mathcal{N}\}$. We identify $p_{\max}(i)$ as the priority class of a connection. The service rate of the bottleneck router is given by μ .

3. COMPUTING THE THROUGHPUTS

We use the well-known relation for TCP rate which characterizes both data as well as real time connections (assumed to be TCP friendly):

$$\lambda_i = \frac{1}{R_i} \sqrt{\frac{\theta}{p_i}}, \quad i \in \mathcal{N} \cup \mathcal{I}, \tag{1}$$

where R_i and p_i are TCP flow *i*'s round trip time and drop probability, respectively. Parameter θ is typically taken as 3/2 (when the delayed ack option is disabled) or 3/4 (when it is enabled). We assume that the rates of connections are not limited by the receiver window.

We model the bottleneck as a fluid² queue. We assume that the buffer size is well dimensioned, i.e. it is sufficiently large so that full utilization of the service rate can be achieved. This gives

$$\sum_{j \in \mathcal{I} \cup \mathcal{N}} \lambda_j (1 - p_j) = \mu.$$
⁽²⁾

The parameters λ_j and p_j are determined from user j choice of priority level. More precisely,

• p_j 's are assumed to be controlled at the RED router; each j, p_j is assumed to be a function of the priority

¹RED punishes aggressive flows more by dropping more packets from those flows. ²In our study, the fluid (deterministic) assumption results

²In our study, the fluid (deterministic) assumption results in a simple yet suitable approximation, see [15].

level of connection j which is determined by user j and which we identify with the price x_j per packet payed by the jth connection.

- If μ were fixed, the p_j would then determine λ_j through (1).
- We can thus view equation (2) as providing us with the rate μ that should be available at the bottleneck link so as to guarantee the performance measures (loss probabilities and throughputs) payed for by the connections.

Next, we define some pricing strategy that gives p_i in terms of the flow rate x_i of connection *i*. From Figure 1 for each *i* the drop probability is

$$p_i = p_{\max}(i)Q, \ \forall i, \qquad \text{where} \qquad Q = \frac{q - q_{\min}}{q_{\max} - q_{\min}}.$$
 (3)

We assume, as already mentioned in the introduction, that q is a fixed target value of the average queue. Note that 0 < Q < 1. We assume that the cost per packet x_i is inversely proportional to $p_{\max}(i)$. Thus $p_{\max}(i)$ is given in terms of x_i by $(\alpha x_i + \beta)^{-1}$ so that

$$p_i(x_i) = \frac{Q}{\alpha x_i + \beta}.$$
(4)

where fixed parameters Q, α, β stand for all connections. In addition, each connection may have a fixed subscription price S, independent of the quality of service.

For the network, the main difference between data connections and real-time connections can be represented in their different utilities, i.e. in the way they perceive quality of service and prices. Data connections using TCP are not sensitive to losses since lost packets are retransmitted allowing to recover packet losses. We thus assume that their utility has a component linear in the throughput and another one related to the costs. The connection utility for user i ($i \in \mathcal{N}$) is thus:

$$U_i(x_i) = \lambda_i(x_i)(1 - p_i(x_i)) - a_i\lambda_i(x_i)(1 - p_i(x_i))x_i - S$$
(5)

where a_i is a parameter representing the weight per unit flow rate of the price component in the utility. We consider a linear utility in this case to reflect that an increase in the throughput always affect significatively user welfare. It can be justified from a mathematical point of view, see [3, Footnote 2]. This also eases the analysis.

For real time connections, we assume that the utility has a component concave in the throughput, another component that represents (direct) sensitivity to losses and a component representing the evaluation of the cost for obtaining the requested priority level. We thus choose the utility function to be:

$$U_{i}(x_{i}) = w_{i} \log_{10} \left(1 + \lambda_{i}(x_{i})(1 - p_{i}(x_{i})) \right) -b_{i}p_{i}(x_{i}) - a_{i}\lambda_{i}(x_{i})(1 - p_{i}(x_{i}))x_{i} - S$$
(6)

with w_i and b_i constant values depending on each connection *i*. As usual, $w_i > 0$ corresponds to a preference parameter. The logarithmic function³ indicates a quality feature of real time connections: user reward do not increase in high flow-rate connections as fast as for slow flow-rate connections (consider for instance a voice or video connection,

after some point the user do not detect significant changes when increasing quality service). Notice the fixed average queueing delay has not been directly considered in the above selected utility functions.

4. OPTIMIZING USER'S PRICES

4.1 A numerical example

We begin with a numerical example. The network parameters are given by Q = 0.5, $\alpha = 10$, $\beta = 200$; the parameters describing data or real time connections are $\forall i \ R_i = 0.05$, $\theta = 1.5$, $a_i = 0.01$. (We do not specify the value of S since it is a constant that does not affect the optimization problem faced by a user.) Furthermore the real time connections are assumed to be such that $b_i = 0.1$ and $w_i = 1600 \ \forall i$. The functions (5) and (6) are depicted in Figures 2-3 as a function of the price x (equivalent to giving the priority level). Their restriction to nonnegative x provides the utilities. We

Figure 2: Utility as a function of the priority for data traffic

Figure 3: Utility as a function of the priority for real time traffic

see that the utility as a function of the priority level x has a clear unique maximum. We shall prove this observation

³It is very common to use concave payoff functions for user utilities, see [4].

in the next subsection for general choices of parameters for data connections.

Below we address the question of how user *i* should select a priority level *x* so that the resulting parameters $\lambda_i(x)$ and $p_i(x)$ maximize its utility. This will determine the reaction of users to a given pricing strategy of the network. In the next section we then introduce the network's utility which will be used to compute the network's pricing strategy that maximizes its utility when taking into account users reaction to that strategy.

4.2 Analysis of the first level optimization problem

Data connections.

We will consider first the connection utility given by (5).

PROPOSITION 1. There exists a unique maximum of $U_i(x_i)$ at $X_i > 0$ for data connections. If

$$a_i < \frac{\alpha}{2\beta} \frac{\beta + Q}{\beta - Q}$$

it is the unique solution of

$$X_i = \left\{ x : \left. \frac{dU_i(x_i)}{dx_i} \right|_x = 0 \right\}$$

i.e.,

$$X_{i} = \frac{1}{\alpha 6} \left(\frac{\alpha}{a_{i}} - 5\beta + Q + \sqrt{\left(\frac{\alpha}{a_{i}} + \beta + Q\right)^{2} + 12Q\left(\frac{\alpha}{a_{i}} + \beta\right)} \right).$$
(7)

Otherwise the maximum is located at $X_i = 0$.

Proof: The partial derivatives of $U_i(x_i)$, $\frac{dU_i}{dx_i}(x_i)$, are proportional to

$$H(X_i, a_i) = \left[\sqrt{\alpha x_i + \beta} + \frac{Q}{\sqrt{\alpha x_i + \beta}}\right] \times \left(\frac{\alpha(1 - a_i x_i)}{2(\alpha x_i + \beta)} - a_i\right) + \frac{2a_i Q}{\sqrt{\alpha x_i + \beta}}.$$
 (8)

The unique solution X_i to $\frac{dU_i}{dx_i}(x_i)|_{X_i} = H(X_i, a_i) = 0$ is given by (7).

We have $\lim_{x_i \to +\infty} \frac{dU_i}{dx_i}(x_i) \to -\infty$; straightforward calculations show that $\frac{dU_i}{dx_i}(0) > 0$ if and only if $a_i < \frac{\alpha}{2\beta} \frac{\beta + Q}{\beta - Q}$, thus the solution X_i corresponds to an absolute maximum of the function $U_i(x_i)$ [18]. Otherwise, if $\frac{dU_i}{dx_i}(0) \le 0$ we have an absolute maximum at $X_i = 0$ because the function $U_i(x_i)$ is strictly decreasing for all $x_i \ge 0$.

Remark that, using this proposition, the drop probability $p_i(X_i)$ is given by

$$p_i(X_i) = \frac{6Q}{\left(\varphi_i + Q + \sqrt{\left(\varphi_i + Q\right)^2 + 12\,Q\varphi_i}\right)}$$

if $a_i < \frac{\alpha}{2\beta} \frac{\beta + Q}{\beta - Q}$, where $\varphi_i = \frac{\alpha}{a_i} + \beta$, and $p(0) = Q/\beta$ otherwise.

Real-time connections.

Similarly to the approach for the data connections, one can numerically get the optimal choice x_i for real-time connections which maximize user utilities $U_i(x_i)$. We have not been able to determine sufficient conditions for uniqueness for real-time connections in full generality; we leave it for future work. Nevertheless, the uniqueness can be observed for instance in Figure 3.

From now, we focus only on data users. To illustrate Proposition 1 we consider the following example. the parameter values Q = 0.5, $\alpha = 10$, $\beta = 20$, $\theta = 1$, $R_i = 0.05$, $a_i = 0.1 \forall i$. The value of $\frac{\alpha}{2\beta} \frac{\beta + Q}{\beta - Q}$ results in 0.2628 > 0.1 = a_i . Figure 4 shows the utility $U_i(x)$ of a single data connection as a function of x for these parameters. The maximum is then obtained at $X_i = 2.06 > 0$ as expected.

Figure 4: Utility as a function of x

Figure 5: Network payoff as a function of a

5. OPTIMIZING THE NETWORK'S PRIC-ING STRATEGY

We assume that the network's payoff is made of two components: a cost which is proportional to the resources it provides, that is to the link rate μ , and a utility that represents its revenues. The latter is assumed to be simply the sum of prices payed by the users. Considering a Stackelberg approach, the network's utility is thus given by:

$$\mathcal{U}_{\text{network}}(a_i) = \sum_{i \in \mathcal{I} \cup \mathcal{N}} (a_i \lambda_i(X_i)(1 - p_i(X_i))X_i + S) - \delta \mu$$

$$= \sum_{i \in \mathcal{I} \cup \mathcal{N}} (a_i \lambda_i(X_i)(1 - p_i(X_i))X_i + S)$$

$$-\delta \sum_{i \in \mathcal{I} \cup \mathcal{N}} \lambda_i(X_i)(1 - p_i(X_i))$$

i.e., it depends on the equilibrium obtained at users' level.

Identical data connections.

Consider N identical data users, i.e., $X_i = X = X(a) > 0$, given by (7), $a_i = a$, $\lambda_i = \lambda$, and $R_i = R$. Network utility $\mathcal{U}_{\text{network}}$ simplifies to

$$\mathcal{U}_{\text{network}}(a) = N \left(aX(a) - \delta \right) \lambda(X(a)) (1 - p(X(a))) + N \cdot S.$$
(9)

As before, the maximum of (9) is obtained by using equation $d\mathcal{U}_{network}(a)/da = 0$. The solution to this expression depends also on δ . In particular, for $\delta = 1$, $\mathcal{U}_{network}(a)$ has a maximum $a = \frac{\alpha}{2\beta} \frac{\beta + Q}{\beta - Q} > 0$. For $\delta > 1$ then it yields $a > \frac{\alpha}{2\beta} \frac{\beta + Q}{\beta - Q}$. In these two cases, i.e., when the optimal parameter a, that the network imposes, satisfies $a \ge \frac{\alpha}{2\beta} \frac{\beta + Q}{\beta - Q}$, the utility of the users has an absolute maximum at X = 0, see Proposition 1. This means that they subscribe to the minimal quality of service: they pay only the subscription fee S and obtain the largest drop probability, Q/β (and hence the minimal throughput). Consider a numerical example, illustrated on Figure 5: a plot of U(a) is given for N = 10 identical data connections, for $\delta = 2$, Q = 20/40 = 0.5, $\alpha = 10$, $\beta = 20$, c = 1, R = 0.05. The maximum then is obtained at a = 0.4708188006 > 0.2628.

At $0 < D < \delta < 1$, it yields a reasonable value $0 < a < \frac{\alpha}{2\beta} \frac{\beta + Q}{\beta - Q}$; the quantity D is such that the absolute maximum is obtained at a = 0, on the interval $[0, \infty)$. In Figure 6a we present a plot for $\delta = 35/100$, where a = 0.0125526875 < 0.2628. We have D = 0.3333. In this case we obtain X = 25.28249042, the cost per packet for the maximum user's utility, see Figure 6b.

6. CONCLUSIONS

In this paper, we have analyzed a Stackelberg game where users choose the price they are willing to pay at a RED buffer in order to discriminate service. With respect to a previous result, we use the fact that there is a fixed target for the average queue length (thus resulting also a fixed average queueing delay). This simplification allows to obtain explicit formulae for the equilibrium priority choices of users. Thanks to those expressions, we are able to solve the Stackelberg formulation of the problem.
